Foreword: The Wetland Book

The venerable lineage of encyclopedic publishing can be traced back to Pliny the Elder's *Naturalis Historia*, which contained chapters on water and aquatic life. Although our terminology regarding and understanding of the aquatic environment has evolved over the past two millennia, one constant has been the need for a multidisciplinary approach to examining these areas. Using an encyclopedic model, this multidisciplinary book builds on an ancient format and adapts it for a modern audience. In this way, *The Wetland Book* builds on a long tradition of scholarly publishing and presents invaluable information for its modern audience.

Wetlands have been around longer than the traditions associated with academic publishing. Wetland management and wise use have been practiced by indigenous cultures in many forms for millennia, and that ancient knowledge about wetlands was often curated and passed down orally or in traditional systems and forms. In modern times, the pressures and threats to wetlands are vastly different in their scope and magnitude. The forms of governance and administration that respond to these pressures and threats have also changed, particularly in their scale as it has been recognized that management takes place up to the level of countries and river basins, rather than simply at the local level.

Internationally, wetland conservation, management, and wise use are promoted through the Ramsar Convention on Wetlands. The countries that have signed onto the Ramsar Convention have recognized the imperatives to work with stakeholders and decision makers beyond the traditional wetland community and to incorporate wetlands into policy-making in other sectors such as water, energy, agriculture, and health. Indeed, in 2008 at the 10th Conference of the Contracting Parties of the Ramsar Convention, the Changwon Declaration was adopted, which contains key messages for wetland conservation, management, and wise use addressed to planners; policymakers; elected officials; managers in the environmental, land, and resource-use sectors; educators and communicators; economists; and health workers. *The Wetland Book* offers a base of knowledge that is intended to reach a similarly broad audience.

The editors and contributing authors to *The Wetland Book* have long experience and deep understanding of wetland science and management. Many have worked with the Ramsar Scientific and Technical Review Panel (STRP), the Convention's scientific advisory body, over the years. This collection of people provides a repository of knowledge that can help meet the challenge of learning about and understanding the value of protecting and managing wetlands.

Making this knowledge more easily accessible, however, has always been difficult. There are physical limitations to how much we can pick a person's brain, and there are limitations to how much a wetland manager out in the field, perhaps with little technical support, can search for, read, and review scientific and traditional knowledge to find answers to pressing questions. Thus, the encyclopedic style of publication remains a viable format for accessing high levels of expertise, including expertise from distant locations with similar landscape and ecological characteristics. *The Wetland Book* provides an in-depth level of knowledge in the form of a handbook to assist those seeking information on the many facets of wetland management.

Of course, reading *The Wetland Book* will not make an individual an expert in all aspects of wetland science, wise use, and governance, a feat which no one publication can deliver. Instead, a truly useful publication should offer an individual the vocabulary to support further inquiry and to find knowledge that is locally, regionally, nationally, or even internationally applicable. It should also allow a reader to know who to ask and what questions to pursue when she or he needs more knowledge to solve a research question or particular management problem. *The Wetland Book* delivers this foundation through two volumes – Vol. 1: Structure and Function, Management, and Methods and Vol. 2: Distribution, Description, and Conservation.

We highly recommend *The Wetland Book*; it provides an unparalleled source of knowledge about wetlands by building on the ancient form of the encyclopedia, revitalized by new technologies for distribution and access. We are also proud to see that many of those who have contributed to the Ramsar Convention over many years or even decades have also contributed their knowledge and wisdom to *The Wetland Book*. Given our personal association with the convention, we also recognize the incredible contribution that the Convention has made to wetland knowledge and look forward to further contributions.

Heather MacKay
Chair, Scientific and Technical Review Panel,
Ramsar Convention on Wetlands, 2005–2012

Ramsar Convention on Wetlands, 2012–2018

Preface

The Wetland Book is a hard copy and online production that provides an unparalleled collation of information on wetlands. It is global in scope and contains 462 chapters prepared by leading wetland researchers and managers. The wide disciplinary and geographic scope is a unique feature and differentiates *The Wetland Book* from the existing wetland literature. The editors have compiled *The Wetland Book* from contributions supplied by authors from many countries and disciplines. Combined, these chapters represent a global source of knowledge about wetlands. Given the number of chapters and the scope of the content, it has been published as two separate books.

The bibliographic detail of two books is given below. Book 1 with 292 chapters covers the structure and function of wetlands, as well as the management and the methods used to investigate them.

The Wetland Book I: Structure and Function, Management, and Methods: edited by Finlayson CM, Everard M, Irvine K, McInnes RJ, Middleton BA, van Dam AA and Davidson NC.

Its companion book, published separately, with 170 chapters is:

The Wetland Book II: Distribution, Description, and Conservation: edited by Finlayson CM, Milton GR, Prentice RC and Davidson NC.

The Wetland Book was developed following discussions with wetland experts from the Scientific and Technical Review Panel of the Ramsar Convention on Wetlands and from the Society for Wetland Scientists. These experts pointed to the rapidly expanding literature on wetlands and enthusiastically proposed the development of a comprehensive information resource aimed at supporting the trans- and multidisciplinary research and practice, which is essential to wetland science and management. They were also seeking an information resource that would both complement and extend the existing literature and in particular provide a compendium of knowledge with contributions from authors around the world.

Aware that wetland research was on the rise and that wetland researchers and practitioners often needed to work across disciplines, *The Wetland Book I* has been prepared to serve as a first port of call for those interested in the key concepts in wetland science and management. This approach was taken to allow individuals and multi- and transdisciplinary teams to search for particular terms and subjects, access further details, and read overviews of topics selected by the editors and expert authors. The content provides a global coverage of wetland knowledge with chapters provided by leading wetland experts with information that spans local and regional issues to the wider body of science that is needed to assist practitioners and enable students to come to grips with one of the world's most diverse and important set of ecosystems. This content is especially important as wetland ecosystems in many parts of the world are under increasing pressure due to degradation from human development, which continues at an alarming rate and will require more effective management and restoration. It draws heavily on knowledge compiled through the formal processes of the Ramsar Convention and associated programs and extends upon information contained in the seminal global assessment of wetlands undertaken through the Millennium Ecosystem Assessment.

Book 1 is organized in three parts, Wetland Structure and Function (coordinated by B.A. Middleton); Wetland Management (coordinated by M. Everard and R.J. McInnes); and Wetland Methods (coordinated by A.A. van Dam and K. Irvine). Each part is divided into thematic sections with one or more overview chapers, supported by articles and case studies providing further information on different aspects of the theme. Each section was developed and collated by section leads, namely M. Acreman, M. Alexander, J.A. Boudell, N.C. Davidson, M. Demissie, M. Everard, C.M. Finlayson, P. Gerbeaux, R. Kumar, R. Lucas, R.J. McInnes, B.A. Middleton, D. Moreno Mateos, R. Slootweg, K. Stevens, and C. Stratford. For Wetland Structure and Function, there are chapters covering: succession; biological adaptations; ecological processes and biogeochemistry; importance of hydrology to wetlands; and landscape ecology. For Wetland Management, there are chapters covering: an overview of wetland management; the international framework for wetland conservation and wise use; wetland law and policy; and management of ecosystem services. For Wetland Methods, the chapters cover: wetland delineation and classification; Earth observation approaches and their application to wetland ecosystems; wetland monitoring and assessment; environmental flows; wetland management planning; wetland restoration and creation; environmental impact assessment; strategic environmental assessment; and economic valuation.

We warmly convey our special thanks to those who have acted as section leads and to all the many authors who gave their time and knowledge of wetlands to support this effort as well as their patience while the large number of chapters were collated and edited. We are proud to have worked with them to produce this book. With the benefit of their unstinting efforts and incredibly rich knowledge, *The Wetland Book I* provides a comprehensive source of information for wetland researchers, students, and practitioners. It specifically provides a much needed information resource to support the many efforts to ensure the wise use of wetlands

globally. It has not only drawn on but also extended the expert guidance and advice that the Ramsar Convention's Scientific and Technical Review Panel has provided for governments and wetland experts alike for almost 25 years. In this respect, the foreword provided by the past and present chairs of the panel is particularly appreciated. In providing the foreword, they have reflected on the wealth of knowledge collated by wetland experts who have worked tirelessly to provide government officials with the knowledge base needed to ensure the conservation and wise use of wetlands around the world.

As editors for *The Wetland Book I*, we personally compliment the many contributors and extend a huge vote of gratitude to our section leads for their incredible contributions to the most comprehensive compendium of knowledge about wetlands ever assembled. In particular, we commend their contributions to the wetland literature and acknowledge their unstinting efforts to compile the many chapters and work with the authors to produce *The Wetland Book*. Their knowledge and efforts are matched by their willingness to share the collated knowledge that is now contained in the *The Wetland Book*.

The publisher is thanked for their foresight in developing the concepts that led to *The Wetland Book* and for providing both a hard copy and online version, with the latter being available for future updating. We recommend *The Wetland Book* to all those interested in the growing international knowledge about wetland science and management of these incredibly valuable but threatened ecosystems.

About the Editors

C. Max Finlayson
Institute for Land, Water and Society
Charles Sturt University
Albury, New South Wales, Australia
UNESCO-IHE, Institute for Water Education
Delft, The Netherlands

Max Finlayson is an internationally renowned wetland ecologist with extensive experience internationally in water pollution, agricultural impacts, invasive species, climate change, and human well-being and wetlands. He has participated in global assessments such as those conducted by the Intergovernmental Panel for Climate Change, the Millennium Ecosystem Assessment, and the Global Environment Outlook 4 and 5 (UNEP). Since the early 1990s, he has been a technical adviser to the Ramsar Convention on Wetlands and has written extensively on wetland ecology and management. He has also been actively involved in environmental NGOs and from 2002 to 2007 was president of the governing council of global NGO Wetlands International.

Professor Finlayson has worked extensively on the inventory, assessment, and monitoring of wetlands, in particular in wet tropical, wet-dry tropical, and subtropical climatic regimes covering pollution, invasive species, and climate change. His current research interests/projects include the following:

- Interactions between human well-being and wetland health in the face of anthropogenic change, including global change and the onset of the Anthropocenic era
- Vulnerability and adaptation of wetlands/rivers to climate change, including changing values and trade-offs between uses and users, considering uncertainty and complexity
- Integration of ecologic, economic, and social requirements and trade-offs between users of wetlands with an emphasis on developing policy guidance and institutional changes
- Environment and agriculture interactions and policy responses/outcomes, and collaboration between stakeholders and policymakers

- Wetland restoration and construction, including the use of artificial wetlands for waste water treatment and the generation of multiple values
- Landscape change involving wetlands/rivers and land use (agriculture and mining) and implications for wetland ecosystem services and benefits for local people

He holds the following associated positions

- Scientific Expert on the Scientific and Technical Review Panel, Ramsar Convention on Wetlands, Triennium 2016–2018
- Ramsar Chair for the Wise use of Wetlands, UNESCO-IHE, Delft, The Netherlands (2014–2018)
- Visiting Professor, Institute for Wetland Research, China Academy of Forestry, Beijing, China
- Editor-in-Chief, Marine and Freshwater Research, CSIRO Publishing
- Chair, Environmental Strategy Advisory Panel, Winton Wetlands Restoration (Australia)

Professor Finlayson has contributed to over 300 journal articles, reports, guidelines, proceedings, and book chapters on wetland ecology and management. He has contributed to the development of concepts and methods for wetland inventory, assessment and monitoring, and undertaken many site-based assessments in many countries.

Mark Everard
International Water Security Network
University of the West of England, Bristol, UK

Mark Everard is associate professor of Ecosystem Services at the University of the West of England (UWE, Bristol) in the UK, as well as a consultant, author, and broadcaster.

Mark has extensive involvement in the development and implementation of ecosystem services and the ecosystem approach since the 1980s. He has particular interests in wetland and water systems, including the many important roles they play in socioecological systems and sustainable or other feedback between human and natural elements of these systems.

Mark's work has included extensive international development work, principally in Africa and India, exploring and helping people optimize their interdependencies with wetlands. He has also served as a policy adviser to UK government around ecosystem and environmental issues, as well as to governments in South Africa, India, and Sri Lanka. However, as the formal policy environment is only as strong as its influence and enforcement, Mark has also worked at local and regional scales particularly in developing countries to learn and out-scale social processes that develop sustainable relationships between people and water resources.

Mark's academic involvement has been extensive, including his most recent role at UWE, and he has also been involved in trustee and advisory capacities with many environmental NGOs. Mark is also a prolific communicator, writing many books, academic papers, and magazine articles targeting a range of scientific, technical, and popular audiences, also making regular contributions to TV, radio, and online media.

Kenneth Irvine
UNESCO-IHE, Institute for Water Education,
Delft, The Netherlands
Aquatic Ecology and Water Quality Management
Wageningen University
Wageningen, The Netherlands

Kenneth Irvine, born in Dublin, has worked on a range of lakes and catchments in Europe and Africa, gaining broad experience of the global challenges facing water and habitat quality. After gaining a Ph.D. in 1987 at the University of East Anglia (UK) for a study on shallow lake food webs, he worked as a nature conservation officer for the UK Nature Conservancy Council, before moving to study ecosystem structure and estimating the secondary production of Lake Malawi in Africa. From there, in 1994 he moved to Trinity College Dublin, Ireland, and spent a decade and a half grabbling with the intricacies of policy and ecology to support the implementation of the EU Water Framework Directive. His alter ego continued to work on the African Great Lakes of Malawi and Tanganyika, and the ecology of the Makgadikgadi salt pans of Botswana. In 2011, he moved to UNESCO-IHE Institute of Water Education in the Netherlands to engage more fully in research and teaching to support capacity development. He heads up the Aquatic Ecosystems Group and their work on, mainly, African wetlands, with other recent work on the capacity development within the Danube basin and for Integrated Water Resource Management in India and Southeast Asia. He continues to learn about the complexities and wicked problems of sustainable use of water and ecosystems.

Robert J. McInnes
RM Wetlands and Environment Ltd.
Littleworth, Oxfordshire, UK

Robert McInnes is an independent chartered environmentalist with over 25 years' experience in wetland-related environmental research, consultancy, and conservation. His main areas of interest in wetlands revolve around three inter-related themes: understanding their biodiversity and the ecosystem services provided to human society; the practical restoration and creation of wetlands for multifunctional benefits; and the development and implementation of wetland conservation and wise use policies and strategies.

He works on wetland-related projects within the UK and overseas and has knowledge extending across a range of wetland types. He regularly publishes articles in peer-reviewed journals, books, and conference proceedings. Prior to working independently, Rob was head of Wetland Conservation at the Wildfowl and Wetlands Trust, UK, and has also worked in ecological consultancy and in academia at the universities of Exeter and London.

Rob has been actively involved with the Ramsar Convention's Scientific and Technical Review Panel since 2008 where he has contributed to the Panel's work on urban wetlands, wetland restoration, wetlands and climate change, and wetland ecosystem services. In addition to undertaking projects on behalf of the Ramsar Convention Secretariat, he has worked for intergovernmental organizations, including UNESCO, CBD, and UN HABITAT, major international NGOS, national and local governments, and private clients.

In addition to his project work, Rob is an active member of the Society of Wetland Scientists (SWS), has been a former president of the European Chapter of SWS, is an associate editor of the society's journal *Wetlands*, and in 2011 was awarded the President's Service Award for the significant contributions he has made in promoting the goals of the society.

Beth A. Middleton
U.S. Geological Survey
Wetland and Aquatic Research Center
Lafayette, LA, USA

Beth Middleton is a research ecologist with the US Geological Survey's Wetland and Aquatic Research Center in Lafayette, USA. Her biogeographical research focuses on the impact of climate and landuse change on wetlands, particularly forested freshwater wetlands. Her most recent studies are on hydrologic remediation and vegetation response, and she applies those findings to natural resource conservation. Her work has contributed to the understanding of world wetland restoration and global climate change and her book *Wetland Restoration, Flood Pulsing, and Disturbance Dynamics* received the Merit Award of the Society of Wetland Scientists. Her dissertation was on monsoonal wetlands in India (Ph.D. Iowa State University) and was the origin of her later research on the implications of shifts in drought cycles on wetland biodiversity. Her writing is extensive with several books and more than 125 research articles.

She is a member of the graduate faculty at the University of Louisiana and an adjunct professor at Louisiana State University. Before moving to USGS, she was a full professor at Southern Illinois University. Currently, she is a member of several climate change advisory committees and management working groups. She has done extensive research on worldwide wetlands including monsoonal wetlands, baldcypress swamps, peatlands, salt marshes, fens, and mangrove swamps. She is a fellow of the National Conservation Leadership Institute. Her Fulbright work was at G.B. Pant University. She has served as a senior visiting professor with the

Chinese Academy of Science working on wetland dynamics in China and is a Sigma Xi Distinguished Lecturer. Also, she has given several high level addresses including the Earth Day talk for the US Consulate in Chennai, India, and a TEDx talk called "Conservation Oblivion" (www.youtube.com/watch?v=8O72jOgTQPw).

Anne A. van Dam
Aquatic Ecosystems Group
Department of Water Science and Engineering
UNESCO-IHE, Institute for Water Education
Delft, The Netherlands

Anne van Dam is associate professor of Environmental Systems Analysis at the UNESCO-IHE Institute for Water Education in Delft, the Netherlands. He holds a Ph.D. in Agricultural and Environmental Sciences (1995) from Wageningen University in the Netherlands. Before joining UNESCO-IHE in 2003, he worked for the International Center for Living Aquatic Resources Management (ICLARM) and for Wageningen University, in various aquaculture and fisheries research projects in the Netherlands, South and Southeast Asia, Africa, and Latin America. His research interests are in the areas of sustainable aquatic resource management, freshwater wetland ecology and governance, nutrient dynamics, and ecosystems modeling. His publications cover subjects like fish growth modeling, periphyton-based fish production systems, integrated agriculture-aquaculture systems, and wetland ecosystem services. During the last 10 years, he had a leadership role in research and capacity development projects in East Africa, with research focusing on the interactions between livelihood activities (e.g., agriculture) and the ecological functioning of papyrus wetlands, collaborating with universities, government agencies, and NGOs in Kenya, Uganda, and Rwanda. He has represented UNESCO-IHE at the Scientific and Technical Review Panel (STRP) of the Ramsar Convention, is an executive editor of the international journal *Aquaculture Reports*, and was guest editor of a special issue of *Wetlands Ecology and Management* on the ecology and livelihoods of papyrus wetlands.

Nick C. Davidson
Institute for Land, Water and Society
Charles Sturt University Albury
New South Wales, Australia
Nick Davidson Environmental, Wigmore, UK

Nick Davidson was the deputy secretary general of the Ramsar Convention on Wetlands from 2000 to 2014, with overall responsibility for the convention's global development and delivery of scientific, technical, and policy guidance and advice and communications as the Convention Secretariat's senior advisor on these matters. He has long-standing experience in, and a strong commitment to, environmental sustainability supported through the transfer of environmental science into policy-relevance and decision-making at national and international scales. Nick currently works as an independent expert consultant on wetland conservation and wise use.

Nick has over 40 years' experience of research on the ecology, assessment, and conservation of coastal and inland wetlands and the ecophysiology and flyway conservation of migratory waterbirds, with a 1981 Ph.D. from the University of Durham (UK) on this topic, and continues to publish on these issues. Prior to his Ramsar Convention post, he worked for the UK's national government conservation agencies on coastal wetland inventory, assessment, information systems, and communications and as international science coordinator for the global NGO Wetlands International.

He is an adjunct professor at the Institute of Land, Water and Society, Charles Sturt University, Australia; was presented with the Society of Wetland Scientist's (SWS) International Fellow Award 2010 for his long-term contributions to global wetland science and policy; chairs the SWS's Ramsar Section; is an associate editor of the peer-reviewed journal *Marine & Freshwater Research*; is a member of several IUCN Commissions and their task forces (World Commission on Protected Areas (WCPA), Species Survival Commission (SSC), and Commission on Ecosystem Management (CEM)); and is an honorary fellow of the Chartered Institution of Water and Environmental Management (CIWEM).

C. M. Finlayson et al. (eds.), *The Wetland Book*,
https://doi.org/10.1007/978-90-481-9659-3_356

Abstract

The Wetland Book 1 is designed as a 'first port-of-call' reference work for information on the structure and functions of wetlands, current approaches to wetland management, and methods for researching and understanding wetlands. Contributions by experts summarize key concepts, orient the reader to the major issues, and support further research on such issues by individuals and multidisciplinary teams. *The Wetland Book 1* is organized in three parts - *Wetland structure and function; Wetland management*; and *Wetland methods* - each of which is divided into a number of thematic sections. Each section starts with one or more overview chapters, supported by chapters providing further information and case studies on different aspects of the theme.

Keywords

Wetland structure · Wetland function · Wetland policy · Wetland management · Wetland methods

Introduction

The Wetland Book developed from conversations with the Secretariat of the Ramsar Convention on Wetlands and members of the Convention's Scientific & Technical Review Panel (STRP) on the status and knowledge of wetlands globally, and the need to provide a compilation of wetland information to complement existing, but often scattered sources. *The Wetland Book* is produced as an online and hardcopy publication in two parts, *The Wetland Book:* 1 – Structure and Function, Management, and Methods*;* and 2 – Distribution, Description, and Conservation. The books will support the work of students, transdisciplinary researchers, natural resource managers and agency staff, engineers, planners, policy advisors, NGOs, and environmental consultants.

The Wetland Book 1 is designed as a "first port-of-call" reference work for information on the structure and functions of wetlands, current approaches to wetland management, and methods for researching and understanding wetlands. The contributions by experts aim to summarize key concepts, orient the reader to the major issues, and support further research on such issues by individuals and multidisciplinary teams. Each chapter draws upon multiple sources of information including primary and secondary literature, including publications and reports by government agencies

and nongovernmental organizations, where appropriate. Chapters are not comprehensively referenced in the style of research papers but rather provide a selection of key sources for finding further information on each topic. Cross-references are provided to help navigate between related chapters in *The Wetland Book.*

Book Structure

The Wetland Book 1 is organized into three parts – *Wetland structure and function; Wetland management;* and *Wetland methods*. Each of these is divided into a number of thematic sections. Each section starts with one or more overview chapters, supported by chapters providing further information and case studies on different aspects of the theme.

For *Wetland structure and function* there are chapters covering: succession (10 chapters); biological adaptations (4); ecological processes and biogeochemistry (7); importance of hydrology to wetlands (8); and landscape ecology (9).

For *Wetland management* there are chapters covering: the international framework (45 chapters); wetland law and policy (42); management of provisioning services (17); management of regulating services (27); management of wetlands for cultural, aesthetic, and associated services (14); and the importance of managing wetland supporting services (6).

For *Wetland methods* chapters cover: wetland delineation and classification (14 chapters); earth observation approaches and their application to wetland ecosystems (17); wetland monitoring and assessment (12); environmental flows (11); wetland management planning (10); wetland restoration and creation (8); environmental impact assessment (9); strategic environmental assessment (3); and economic valuation (6).

The main topic coverage of each part of *The Wetland Book 1* is further summarized below.

Wetland Structure and Function

This part of the Book provides basic information of key importance to the understanding of wetlands. It progresses from large scale ecosystem and landscape concepts to those of a progressively finer scale including biogeochemical, biological, and physiological/anatomical considerations of plants.

Wetland Succession A general chapter on succession, a topic which forms the underpinnings of wetland change and function over time is provided (Middleton 2018) and includes a short chapter on historical ideas of hydrosere (i.e., Clementsian) succession or wetland change over time toward drier land. Later thinking led to the modern Gleasonian perspective, examining the role of disturbance and species life history dynamics in succession. The US $10,000 succession challenge describes the prize offered in the 1950s by the eminent ecologist Frank Egler to anyone who could demonstrate Clementsian succession leading to a climax community. Although the idea of successional stages leading to a climax community has only weak evidence, the concept is still often used in teaching succession concepts to introductory students of biology (e.g., at high school and first year college level). The debate over the nature of succession (Clementsian vs. Gleasonian) has relevance to more recent discussions of self-design versus designer approaches in restoration practice. A number of specific examples explain how anthropogenic disturbance drives vegetation change, for example cattle grazing in wetlands. Whereas fire can be a natural disturbance in wetlands, the human impacts of drainage, cutting and climate change are creating unnaturally destructive peat fires in swamp forest in South-east Asia. Differences in the succession process are apparent in coastal settings, and comparisons are made with fresher water settings.

Landscape Ecology Landscape ecology has emerged relatively recently as a new field in wetland ecology, as broad scale drivers have been increasingly acknowledged as influencing wetland processes (Boudell 2018). Chapters describe various elements of wetland landscape ecology including the concepts of connectivity, corridors, fragmentation, and patch. Process concepts are covered in chapters on disturbance, ecosystem function, and gap and patch dynamics. Species reassembly in riparian and other wetland systems differ because of underlying differences in landscape dynamics in those settings. Practical applications of these concepts are given in chapters on riparian zone buffers, source-sink dynamics, wetland restoration implications, and the heterogeneity of wetland processes as molded by landscape setting. The dynamic nature of wetland processes controlled from a variety of scales lends complexity to the nature of population genetics across wetland landscapes.

Ecological Processes and Biogeochemistry General aspects of chemical transformations in wetlands dictate the nature of other processes (Baldwin 2018). The nature of wetland chemical transformations has important influences on various ecosystem processes, including carbon flux, photosynthesis, primary production, and respiration. Wetland processes related to water quality improvement and habitat support provide vital services to humans, and approaches have been developed to evaluate the economic value of wetlands to human communities. Wetland degradation can negatively impact the extent of ecosystem services provided by wetlands. Therefore, various agencies have implemented programs to better develop policy to protect wetlands including Ecosystem Service Partnerships, the Intergovernmental Science-Policy Platform on Biodiversity and Ecosystem Services (IPBES), and the Millennium Ecosystem Assessment.

Hydrology for Wetlands: Importance How water dynamics dictate wetland function is described in Rasmussen (2018). These processes play out rather differently in coastal wetlands because of their proximity to the ocean. Due to the complex processes associated with various water inputs and outputs, hydrologic modeling helps frame our basic understanding of wetland hydrology. A specific case of hydrologic dynamics as it relates to treatment performance in constructed wetlands is provided for the Everglades region in Florida, USA.

Biological Adaptations Finer scale considerations of wetlands are summarized, including the anatomical (Seago 2018), morphological (Schaffer 2018), and physiological (Kandalpas 2018) adaptations of plants to life in an aquatic environment. Some aquatic species succeed in environments that terrestrial species would find harsh, by engaging in symbiotic relationships with microbes.

Wetland Management

Information provided on wetland management will be useful to audiences interested in approaches for managing wetlands, including how these approaches have changed over time with the development of international frameworks and newer concepts, such as the developing focus on ecosystem services and the adoption of the 2030 Sustainable Development Goals (SDGs). The importance of legal structures and policy settings is also explored.

Overview of Wetland Management Management of wetlands is complex, needing to address both the pressures imposed on wetlands by wider landscape change as well as more direct *in situ* pressures and measures needed to retain a wetland's natural character and ecosystem services. There is a long history of wetland management, for example to protect favored birds and other species or for fishery, recreational, and other uses. However, in the main, wetland management has not historically been undertaken with conscious efforts to optimize the multiplicity of interconnected ecosystem services providing benefits to diverse sectors of society and underpinning system resilience. Everard (2018a) explores the need for systems scale thinking in wetland management, ensuring that management maximization of single or narrow subsets of benefits does not occur at net cost to wider system functioning and optimization of human well-being across a range of linked ecosystem services.

International Framework for Wetland Conservation and Wise Use Such is the importance of wetlands and their ecosystem services that they are the subject of a wide range of international conventions and agreements and others mechanisms for protection and positive management (reviewed by Gardner 2018). These include biodiversity-related conventions, of which the Ramsar Convention on Wetlands is an international exemplar (Davidson 2018). The multiple values they provide to society also mean that wetlands have been a focus of the Convention on Biological Diversity, as well as making important contributions towards achieving global biodiversity targets.

Wetlands also have significant international ramifications, both as transboundary systems and as networks of habitats vital for migratory species. For this reason, a range of transnational and regional legal frameworks has been established, particularly with respect to integrated management of migratory bird flyways (Davidson and Stroud 2018). Regional legal frameworks have also been developed for the comanagement of significant international and interregional wetlands such as Lake Chad and the Murray-Darling Basin, Australia.

Significant implications for wetland management also arise from global challenges such as climate change and the commitment by UN signatories to the 2030 Sustainable Development Goals (SDGs).

A range of nongovernmental organizations (NGOs), institutions, and programs, across a range of scales, have particular focal interests in wetland conservation and management including, for example, BirdLife International, the International Crane Foundation, the International Peat Society, the Society of Wetland Scientists and Wetlands International. Some institutions have government backing and support for significant wetland rehabilitation programs, such as South Africa's national wetland rehabilitation program called *Working for Wetlands*.

Wetland Law and Policy Wetland management needs and initiatives have given rise to a diversity of wetland law and policies (Gardner and Finlayson 2018), including a wide range of national wetland policies (Bonells 2018). These policies encompass a range of principles including "no net loss," different types of permit schemes, the "avoid-mitigate-compensate" sequence and mitigation banking. Management tools such as Environmental Impact Assessments and Strategic Environmental Assessments support impact assessment and mitigation measures.

Economic values as well as diverse non-market benefits associated with wetland ecosystem services mean that management occurs within economic, ecological, and social contexts. Economic incentives may be significant for the nonregulatory conservation and management of wetlands (Watts and Everard 2018). Financial exchanges may have a role to play in incentivizing land owners to retire land or to manage in ecosystem-sensitive ways; examples include the US Conservation Reserve Program and the Payments for Ecosystem Services (PES) approaches. Establishment of national wetland policies is a strategic priority for signatories to the Ramsar Convention. Consequently, many countries have developed wetland policies and examples are described from Australia, Ghana, Chile, and the USA.

Management of Provisioning Services Management of wetlands for provisioning ecosystem services can encompass a diversity of outputs (Everard 2018b) including, for example, wetland food (such as lake bed cropping), reed products, traditional medicines, and salt production.

Management of Regulating Services Wetland management for regulatory services (McInnes 2018) also encompasses a diversity of benefits including support of insect pollinators, climate regulation, coastal protection, and urban wastewater management.

Management of Cultural Services Cultural services as foci for wetland management (Papayannis and Pritchard 2018) cover a diversity of benefits such as protection of archaeological resources, religious interests, educational resources (including visitor centers), and inspiration for the arts.

Importance of managing wetland supporting services Often overlooked, certainly by traditional economic assessment as they are not directly "consumed" in the economy, management of wetlands for their supporting services is essential for maintaining ecosystem integrity, functioning, and a reliable flow of other services (Everard 2018c). These services include nutrient cycling, biodiversity support, and generation of soils.

Wetland Methods

This part of the Book will be useful to a diverse audience. For those who work with wetlands, it can serve as an entry point to more detailed technical publications on the practical application of these methods. For students and decision makers, it will support a broad understanding of how wetlands are measured, mapped, and valued; how changes in wetlands can be assessed; and how planning for management and protection can be improved.

Wetland Delineation and Classification With the introduction of formal protection of wetlands by means of policies and laws, the need for formal delineation, mapping, and inventory arose. Tiner (2018) describes how this is done in the USA, a country with one of the longest traditions in wetland identification and delineation. Three types of indicators (on hydrophytic vegetation, hydric soil, and wetland hydrology) can be used to characterize wetlands. Aerial photography and, more recently, geographical information systems and satellite imagery play a large role in incorporating these indicators into the maps of wetlands.

Another need arising from formal protection and management procedures is the classification of wetlands (Gerbeaux et al. 2018). A variety of classification systems for wetlands has evolved, based on different characteristics of the wetland such as soil or vegetation type, geomorphology or nutrient status. Several chapters present different classification systems for specific types of wetlands (e.g., coastal wetlands, peatlands, and estuaries) or for specific countries (e.g., Brazil, Canada, India, South Africa, and the USA). A separate chapter describes the Ramsar Convention's classification system.

Earth Observation Methods for Wetlands In this section earth observation approaches, and their application to wetland ecosystems, are covered. An overview is given by Lucas (2018a). Since the 1970s, sensors operating in the visible and infrared regions of the electromagnetic spectrum (e.g., the Landsat satellites) have provided valuable imagery for characterization of wetlands and their dynamics. More recently, sensors in the thermal and especially the microwave region of the spectrum have also become important, especially because the latter (e.g., Synthetic Aperture Radar, SAR) can observe changes in water dynamics regardless of cloud cover or overhanging canopies. Separate chapters provide more in-depth insights into different sensor types (Lucas and Costa 2018) and the electromagnetic spectrum (Lucas 2018b) and into the use of remote sensing for observing water persistence and duration (Milne 2018). Other chapters focus on remote sensing applications for a variety of wetland types (arctic and boreal wetlands, tropical forest wetlands, seagrasses, mangroves, peat swamps, subtropical wetlands, temperate bogs, mires, and fens) and human activities related to wetlands (aquaculture, agriculture).

Wetland Monitoring and Assessment One of the assumptions of protection and management is that information on the state of the wetland, and especially on the characteristics of the ecosystem which are part of management objectives, is available. This leads to the need for monitoring and assessment of wetlands (Stratford 2018a). Different types of assessment (hydrological, biological, functional, integrated, and vulnerability assessment) are discussed. While assessment is often a "snapshot" observation, monitoring (Stratford 2018b) provides more long-term data on the changes of the wetland, often based on very specific monitoring objectives (e.g., related to pressures on the ecosystem or to the effectiveness of management measures).

Environmental Flows The extraction of water from aquifers, rivers, lakes, and other wetlands for human use and the observed impact on ecosystems have led to the realization that there is a trade-off between the quality of ecosystems and the benefits of water for humans. The environmental flows concept is introduced by Acreman and Arthington (2018) and deals not only with the quantity of water available for ecosystems but also with water quality and the timing of flows. This is a complex issue, as it involves the challenge of determining the water requirements of the ecosystems, the practical questions around safeguarding these flows, as well as the policies and management strategies needed for implementing them. Subsequent chapters discuss various frameworks developed over the past decade for quantifying and realizing environmental flow regimes with examples of their implementation, and place the environmental flow concept within the context of integrated water resources management.

Wetland Management Planning As a result of increasing awareness of the importance of wetlands, and supported by the Ramsar Convention, increasing numbers of countries have formulated and adopted wetland conservation policies (see chapters in the "Wetland Law and Policy" part). The impact and effectiveness of such policies depend crucially on how they are translated into actual management on the ground. For this, management planning is extremely important. Alexander (2018) introduces the planning process which starts with the formulation of a clear vision and objectives, and participation of all involved in the wetland site. Other chapters discuss the planning process and which tools can be used. Emphasis is on adaptive management which allows frequent reassessment of objectives and actions to adjust the process to changing circumstances and needs. A separate chapter covers approaches to increase the capacity of countries to implement the management planning process, and several case studies are presented to support this topic.

Restoration and Creation of Wetlands Sometimes it is not possible to protect wetlands from degradation or destruction, and increasingly efforts are being made to restore degraded wetlands and even create new ones. Moreno-Mateos (2018) shows that, although restoration cannot bring back the original ecosystem, it is possible to restore some of the important ecosystem functions and services that the original wetland system provided. Restoration can lead to artificial new wetland ecosystems ("constructed wetlands"), to brand new natural wetlands which are allowed to develop independently ("created wetlands"), or to the recovery of existing wetlands from earlier anthropogenic impact. Chapters discuss the ecosystem aspects of restoration (e.g., water quality, succession and plant communities, carbon and nutrient cycling), policy-related topics, and the economics of wetland restoration.

Environmental Impact Assessment for Wetlands Human development and economic activities create pressures on nature that, through the years, have led to the degradation and destruction of ecosystems all over the world. Concerns over negative impacts on the environment (including wetlands) in the 1960s led to the development of Environmental Impact Assessment (EIA) as a process to influence decision-making about development projects and to mitigate negative effects on not only ecosystems but also on society in a broader sense. Slootweg (2018a) introduces EIA and its development, including how it plays a role in policy and practice for wetland protection and conservation. In the following chapters, the various stages in the EIA process (screening, scoping, assessment and evaluation, reporting, and decision making) are explained further. Separate chapters are devoted to mitigation and to health and social impact assessment, as well as to the vital need for the participation of stakeholders in the EIA process.

Strategic Environmental Assessment for Wetlands While the EIA process is usually applied at the project level, Strategic Environmental Assessment (SEA) has been developed as a set of tools to identify and address the environmental and social impacts of higher-level initiatives such as policies and programs. SEA became important in the 1980s and 1990s, and Slootweg (2018b) describes its importance for wetlands, as demonstrated by the fact that EU member states have had since 2006 a legal obligation to apply SEA to their development plans and programs. Further chapters discuss the background and scope of the SEA process, including what is needed to implement the SEA process effectively for improved and more integrated decision-making for wetlands and their resilience.

Economic Valuation of Wetlands One of the topics that has received a lot of attention during the last decade is the economic valuation of ecosystems. Propelled by initiatives such as the Millennium Ecosystem Assessment and the "*The Economics of Ecosystems and Biodiversity*" (TEEB) economic valuation of ecosystem services has become part of the mainstream in policy and decision-making for wetlands. Kumar (2018) explains the background principles of economic valuation and highlights some of the challenges, e.g., of upscaling of values obtained from limited studies and uncertainty related to the limitations of the methods used for valuation. Subsequent chapters deal with the total economic value of wetlands and provide more details on the different valuation methods. Two separate chapters discuss market-based and policy-based instruments to incorporate the economic value of wetlands in policies for wetland conservation and protection. A final chapter presents a number of examples of wetland valuation studies.

Succession in Wetlands

2

Beth A. Middleton

Contents

Abstract

Succession refers to the change in vegetation over time driven by disturbances and the maturation of plant species. In wetlands, these disturbances include water and salinity level changes along other factors that can alter vegetation. The historical view of succession (Clementsian) was that vegetation change represented the linear progression of through stages of vegetation toward a climax state. These stages were thought to be comprised of species that were interlocked with each other. These days the idea that succession is represented by the successive replacement of highly related sets of communities over time has been deemphasized, in favor of the idea that species in the community act more independently of one another (Gleasonian). An important example of this Gleasonian perspective model has been developed for prairie wetlands of North America by van der Valk. In this view, succession proceeds in a cyclic fashion, with flooding and drought driving changes in specific species, so that the individualistic species responses to water regime and other disturbances drive changes in the system (Environmental Sieve Model). The succession of

many other world wetlands types is thought to occur in a similar way. These recent ideas of succession emphasize that species that are able to regenerate after disturbance via seed banks and propagules, and that the nature of post-disturbance regeneration is the most important determinant of later succession (initial floristics). Notably, the idea that lakes and bogs represent an early state of succession, and that depressions fill in to become dry land (terrestrialization) has little evidence. With climate change, wetlands are likely to have altered successional trajectories, particularly as these ecosystems become exposed to different climatic temperatures, flooding/drought cycles, salinity intrusion and increased CO_2.

Keywords
Clementsian succession · Gleasonian succession · primary succession · secondary succession · relay floristics

Definitions

Allogenic succession is the change in ecosystems related to abiotic influences. Environmental constraints are thought to be the most important delimitors of succession.

Autogenic succession is the change in ecosystems due to biotic influences.

Clementsian succession is the idea that vegetation in communities changes over time through successive stages by allogenic and autogenic processes until a climax stage is reached. Although the idea is often portrayed in textbooks, it is not widely held by ecologists. As an example of an ecosystem that does not have seral stages, baldcypress trees establish after seed germination in the light gaps of tree falls or old fields. Once established, the trees can live for centuries.

The climax stage is the final outcome of succession following the ideas of Clementsian succession.

Preemption is a common type of competition where individuals that occupy a space make it difficult for individuals of other species to invade that space. Preemption is likely the most important type of competition, although resource competition is often the focus of studies.

A functional group is a set of organisms with similar traits, roles, and responses to disturbances in ecosystems. The response of the functional group can be considered as typical of the set of organisms.

Perturbation is very similar to the term “disturbance” for most ecologists. Some ecologists define perturbation as a disturbance that is not natural in the ecosystem, e.g., a human disturbance.

Resilience is the relative ease of ecosystem recovery after disturbance. Some systems are repeatedly impacted by hurricanes, salinity intrusion, or

(*continued*)

Forest change in subarctic environments may be limited by freezing and flooding. Pictured is a peatland in the Sanjiang Plain of northeastern China (Photo by Beth Middleton)

other disturbances but quickly return to their original ecosystem type and function.

Persistence is the existence of an ecosystem type despite repeated disturbances. Gleasonian succession is the idea that vegetation in communities changes over time in response to disturbance. Following this idea, succession is viewed as the response of species to environmental conditions with respect to maturation and fluctuation. Hydrarch succession is the idea that a lake can fill in to become dry land. This old concept is challenged by most ecologists, who more likely favor the idea that left to natural succession, once a wetland, always a wetland. Also, it is more likely that dry land will become a wetland through paludification than that a wetland will become dry land through hydrarch succession.

Primary succession is vegetation establishment on a site that has not had vegetation before e.g. a site with volcanic outfall or a new shoreline.

Secondary succession is vegetation change on a site where vegetation has occurred before e.g. old field succession community or ecosystem change over time.

(*continued*)

Old growth baldcypress in Cat Island National Wildlife Refuge near St. Francisville, Louisiana. Trees of this species are the first to germinate and establish on the edges of swamps in old field settings. Pictured is Evelyn Anemaet (Photo by Beth Middleton)

Chronosequence is the concept of space-for-time substitution, which attempts to demonstrate that zonation patterns lying along a gradient demonstrate succession over time. This approach has been largely invalidated.

The Environmental Sieve Model is the idea that species may be blocked (sieved) from a site because of a lack of tolerance for the environment by various life history stages of a species. In wetlands, the water tolerance of the life history stages of species is important in determining successional outcome.

Facilitation is the idea that certain species can colonize harsh environments, and thereby enable the colonization of other species.

Initial floristics refers to the idea that the species originally establishing in a site after disturbance set the long-term successional pattern. Following this idea, after establishment, vegetation change is thought to be mainly an outcome of the maturation of the established individuals. Generally, the majority of species that come to occupy an ecosystem are present immediately after the disturbance.

(*continued*)

After species establish on a site, it is difficult for others to establish because they are preempted from occupying the space. Pictured is Evelyn Anemaet standing inside of the trunk of an old growth baldcypress tree, Cat Island National Wildlife Refuge, St. Francisville, Louisiana (Photo by Beth Middleton)

Life history attributes are the traits that lead species to respond in particular ways to environment as based on the characteristics of each life stage (i.e., seed set, dispersal, germination, and growth of seedlings and adults).

Paludification is the process by which dry land becomes a peatland following the invasion of hydrophilic mosses. After the invasion of these mosses, the water table rises, and subsequent drainage is impeded by the accumulation of peat.

Pioneer species are those that establish quickly in communities after disturbance.

The reductionist concept of succession places an emphasis on the role of species traits in ecosystem processes e.g. the emphasis on individual life history characteristics in Gleasonian succession.

(*continued*)

Tupelo and baldcypress (*left and right*, respectively) are tree species of the same functional group, which occupy similar habitats and respond similarly to environment. Pictured is a swamp forest in Cat Island National Wildlife Refuge, St. Francisville, Louisiana (Photo by Beth Middleton)

Relay floristics describes succession as a process characterized by a sequence of stages (successional seres), each successively creating the conditions necessary for the following stage. This idea of succession emphasizes autogenic processes, that is, that the organisms themselves are changing the conditions on the site.

A safe site is a place where seed germination and species regeneration can be successful following disturbance. Light gaps in a forested wetland may provide a place for seed germination for some plant species depending on environmental constraints such as flooding and salinity level.

A seral stage is one of a sequence of successional stages thought to prepare the way for subsequent stages in Clementsian succession. Seral stages have been largely discounted in successional theory. Instead, the idea that each species establishes and matures independently of others during succession is currently more favored among ecologists.

(*continued*)

Pictured is a fire in a wetland in Rajasthan, India (Photo by Beth Middleton)

Stability in an ecosystem reflects its ability to return to its original condition after disturbance.

The steady (stable) state is a relatively unchanging vegetation status over time.

The superorganism concept is the idea that a community is an entity with unit characteristics more important to function than the individual species comprising the community, i.e., the sum is larger than the parts. In succession, this idea corresponds to the notion that seral stages are characterized by species that move together as a unit through time and space.

Terrestrialization is the filling-in of a lake to become a bog. In actuality, the process of paludification is more likely to turn dry land into a wetland.

Water regime refers to the water dynamics of a wetland ecosystem (or experiment) including water level, periodicity, and flow.

Introduction

Succession refers to species change over time as related to the maturation and fluctuation of species (van der Valk 1981). In wetlands, these changes are driven by natural disturbances such as water and salinity level fluxes, herbivores, fires,

Resilient ecosystems return to their original state after a specific type of disturbance. Pictured is a mix of *Phragmites* and baldcypress swamp species along the Pocomoke River after Hurricane Sandy. Note that some of the baldcypress trees to *left* appear to have died (Photo by Beth Middleton)

windstorms, hurricanes, and earthquakes. Historically, the view was that natural disturbance interrupted the progression of succession toward a climax state and that each successional (seral) stage was comprised of a set of interlocked species (Clements 1916). This successional progression was viewed as a product of largely autogenic processes on the part of this unit of interlocked species. Over time, these species were thought to fill the open water of the basin with organic materials until the wetland became dry land, which was seen as a largely autogenic process. This Clementsian idea of succession is no longer wholly accepted. In fact, notions of regional climax, terrestrialization, and seral stages of communities have been deemphasized in modern views of succession (Niering 1987).

Drivers of Succession

These days, a widely held idea of succession is that disturbance drives successional changes in plant communities and that the species in the community act independently of one another (Gleason 1926). A succession model following

Primary succession occurs in places where vegetation has not occurred before, for example, on rocks along new shorelines. Pictured is a shoreline of Hudson Bay, near Wemindji, Quebec, Canada (Photo by Beth Middleton)

these Gleasonian ideas was developed for prairie pothole wetlands in North America (van der Valk 1981) and monsoonal wetlands in Australia and India (Finlayson 1991 and Middleton 1999, respectively). The van der Valk model of wetland succession proceeds in a cycle that maintains wetlands over many millenia, with the key drivers of succession related to disturbance (Fig. 1(1, 2)). The cycle proceeds as vegetated freshwater marshes are destroyed by disturbances such as high water and herbivory. After the vegetation is killed, the wetland becomes an open marsh. The open marsh is maintained for many years because the emergent vegetation cannot germinate in flooded conditions, preventing the development of new emergent vegetation. Emergent vegetation reappears in the wetland during drought, which recurs at 5–25 year intervals. During drought, the wetland draws down resulting in the reemergence of mudflats. In these mudflat conditions, emergent (e.g., cattail) and other mudflat species can germinate and reestablish (Fig. 2). When normal rainfall resumes, the emergent species regrow into the water column (regenerating marsh stage). Eventually, high water and herbivores remove the emergent vegetation (open marsh stage), and the cycle begins again (Fig. 3).

Similar succession patterns occur in other freshwater wetlands around the world, with the timing of drought/reflooding patterns key to the timing of vegetation reestablishment. Monsoonal wetlands in India, Africa, Australia, and South America

Zonation patterns in wetlands do not necessarily represent succession over time. Pictured are zones of *Phragmites* and mixed swamp forest along the Pocomoke River in Maryland (Photo by Beth Middleton)

often have annual cycles of drought/reflooding, so that the succession cycle occurs in a shorter time frame (Fig. 4) (Middleton 1999).

Within the context of hydrologic dynamics in relationship to the establishment and maintenance of wetland species, multiple steady states may persist in wetlands such as the Everglades (Zweig and Kitchens 2009). Furthermore, the growth of the runners of certain salt marsh species in bare areas demonstrate the facilitation of the colonization of less tolerant species because the facilitating species make conditions less harsh (e.g., lowers salinity; Crain et al. 2008).

Many species establish immediately after disturbance, so that subsequent changes in vegetation may be because of the development of taller species, which are a part of the initial floristics of a site (Niering 1987). The initial floristics concept suggests that most species are present as seeds or propagules in the soil after disturbance (Niering 1987). Shrubs and trees may not be apparent in the early stages of secondary succession, but later, these taller species develop and dominate the community. A good example of the importance of initial floristics during secondary succession is on Alaskan floodplains. Pioneer species (willow, poplar, alder) and late-forest species (spruce) are both present on these floodplains almost immediately after

Tree species typically cannot establish in permanently flooded conditions e.g. baldcypress seeds only germinate in unflooded environments. Pictured is the impounded Buttonland Swamp in southern Illinois with little tree regeneration (Photo by Beth Middleton)

agricultural abandonment, but the late-forest species become dominant later. Also note that primary succession is similar to secondary succession, except that primary succession occurs on sites where vegetation has not occurred before, e.g., lake margin of newly formed volcanic crater.

Seral Stages or Not

Wetland zonation patterns sometimes are used to demonstrate seral stages of wetlands, but this idea has also been challenged (Niering 1987). Chronosequences or space-for-time substitutions have been invalidated with analyses examining long-term vegetation studies, palynology, and other related approaches. These studies show that the inferred seral stages are not related to vegetation change over time (Johnson and Miyanishi 2008). Changes in the structure of the wetland zones around lakes, bogs, and tidal marshes actually are the product of water level changes related to climate or edaphic factors, including beaver activities (damming and tree cutting) (Niering 1987).

After Hurricane Katrina, many coastal wetlands returned to their prehurricane condition. Pictured is a brackish marsh a few weeks after Hurricane Katrina along the Pearl River in Mississippi (Photo by Beth Middleton)

That lakes or bogs could infill was once used as an example of seral stages in succession (Klinger 1996). For example, it was thought that seral stages including *Sphagnum* and a series of other seral stages could bring the site to an ever-drier state toward an upland forest (terrestrialization). Instead, many studies show that once a bog forms, it is likely to remain as a bog for thousands of years. It is more likely that dry land will become invaded by *Sphagnum* by paludification and become a bog. Therefore, a bog should be viewed as the end point of vegetation change (Klinger 1996).

Disturbance Models and Succession

Disturbances act on the vegetation by removing the dominant vegetation, so that disturbances can maintain biodiversity in wetlands by giving nondominant species a window of opportunity to grow. The species that can occupy a wetland after a disturbance depend on the environmental conditions related to water/salinity regime, soil conditions, and other environmental constraints. Species have very specific abilities to establish after disturbance depending on their life history characteristics. The environmental sieve model suggests that the species composition of a wetland

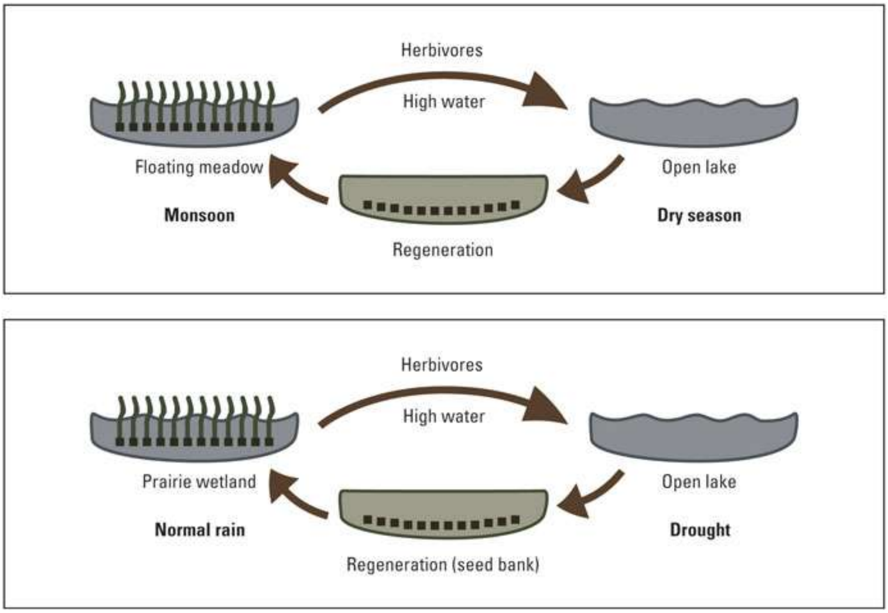

Fig. 1 (**1**) Monsoonal wetlands in northern India flood during the monsoon (October through March) and drawdown during the dry season (April through July), thereby completing a vegetation cycle in 1 year. If the monsoon fails, the wetland stays dry until the next monsoon, unless water floods the floodplain from the river (van der Valk 1981). (**2**) The vegetation cycle in prairie potholes in North America occurs over a 5–25 year interval and is also driven by periodic drought. Some species of monsoonal wetlands and prairie potholes live for decades in the seed bank, which preadapt these species to survive any long-term drought related to climate change (Middleton 1999)

depends on the life history requirements of the species and their adaptation to the specific environments of wetlands. Certain species are periodically "sieved" for a time from a wetland depending on the conditions in the wetland and the tolerances of the species for those conditions (van der Valk 1981).

Models have been developed to predict which species will grow in response to flooding versus drawdown (Figs. 4, and 5(1, 2); van der Valk 1981; Middleton 1999, Finlayson et al. 1991). The main determinants for species development following disturbance depend on the ability of the life history stage of a species (seed, seedling, adult) to grow in various water regimes (flooded versus drawndown) and if the species is annual or perennial (Fig. 4). Species of similar types transition in response to flooding versus drawn down conditions in wetlands, although the particular species may vary regionally. For example, in communities of native rice, *Oryza* is an annual species, which establishes in standing water (AS-II). The particular species may vary by region or continent (e.g., Australia and India: *Oryza australiensis* vs. *Oryza rufipogon*, respectively; Fig. 5(1, 2). (Finlayson 1991 and Middleton 1999, respectively).

Fig. 3 Open water in freshwater marsh in the Okavango, Botswana. Large herbivores such as hippopotamus maintain hemimarsh in some African wetlands (Photo by: Beth Middleton)

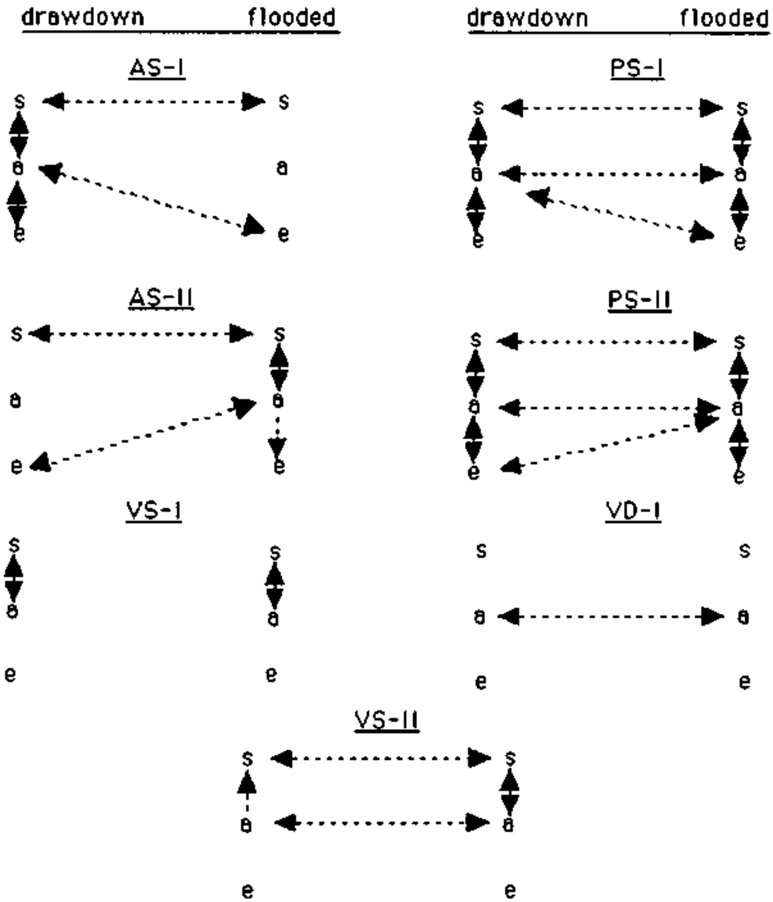

Fig. 4 Predicted transitions in flooded and drawdown states (increasing versus decreasing, respectively) in monsoonal wetlands. Transitions are represented by *solid* and *dashed lines* between environmental states (within versus between states, respectively). The species types are: s = present as long-lived propagules in a persistent seedbank; *a* = mature adults; and *e* = locally extinct. Other letters and symbols are defined in Fig. 5 (From Finlayson 1991, reprinted with permission of the author)

Future Challenges

Wetland ecosystems altered by climate change in the future may experience different successional trajectories than the current ones, particularly if climates change as predicted by the IPCC (2007), so that these ecosystems are exposed to increased CO_2, temperature, salinity, or flooding-drought episodes.

Environmental Sieve Model of Wetland Succession

3

Arnold van der Valk

Contents

Abstract

In the first environmental sieve model, water level (standing water, no standing water) determined which species could become established and which would be extirpated at a given time in a wetland. Species attributes were used to predict what would happen to each species in a wetland as water levels changed. The three attributes used were: (1) life expectancy (annual, short-lived perennial, and perennial with vegetative growth), (2) seed dispersal (seeds present in seed bank, seeds had to be dispersed to wetland), and (3) seed germination requirements (seeds can germinate underwater or seeds can germinate only on wet soil). The model was tested successfully in a long-term, water manipulation study carried out in the Delta Marsh in Canada, the Marsh Ecology Research Project (MERP). More sophisticate versions of this type of model have been developed that can make quantitative predictions about changes in the composition of wetland vegetation over time.

Introduction

What causes temporal changes in the species composition of vegetation over time (succession) has been one of the central problems in ecology since its origins as a science in the late nineteenth century. German ecologists were the first to postulate that it was the morphological, anatomical, and physiological characteristics of plant species that adapted them to a specific climate or micro-environment (van der Valk 2011). Although this approach provided an explanation for why some species are found in the tropics and others in the arctic and why vegetation changes when climates changed over geologic time, it did not explain how a given species became established or why it might disappear from a particular site over much shorter time intervals. To understand this required additional knowledge about the characteristics of species in the local flora that was ecologically rather than geographically and geologically relevant (Grime 1979): how a species is dispersed, the conditions under which it can become established, its life expectancy, its growth rate, how it responds to various kinds of disturbances, etc. These ecologically relevant characteristics of plant species came to be called their vital attributes (Noble and Slatyer 1980). One of the first attempts to use this approach for understanding and predicting vegetation change was developed in the 1950s by Frank E. Egler (1954). He proposed that light requirements for seed germination and seedling growth were largely responsible for the changes in vegetation observed during old-field succession in New England. This approach was expanded in the 1960s, 1970s, and 1980s by terrestrial ecologists (Grime 1979; Noble and Slatyer 1980) and applied to wetlands by van der Valk (1981). The use of community assembly rules (Weiher and Keddy 1999; Toth and van der Valk 2012) to predict vegetation composition and change is a closely related approach.

Vital Attributes

In wetlands, many vital attributes of species have been identified that can be used to predict when they can become established and when they will be extirpated. These include seed dispersal (present in seed bank, not in the seed band (dispersal dependent)); seed establishment requirements (germinate only on mudflats, germinate only under water, will not germinate in shade, etc.); types of vegetative growth (long vs. short rhizomes, turions, terrestrial form, etc.); and life expectancy (annual, short-lived perennial, long-lived perennial). For example, van der Valk (1981) was able to predict when species with certain vital attributes would become established and when they would be extirpated during wet-dry cycles in prairie potholes in North America (Fig. 1). Only three vital attributes were needed (Fig. 2): life expectancy (A – annuals, P – short-lived perennials, and V perennials with vegetative growth); seed dispersal capacity (S –seeds in seed bank, D –seeds not in seed bank); and germination requirements (type I – seeds germinate only when there is no standing water, II – seeds germinate under water).

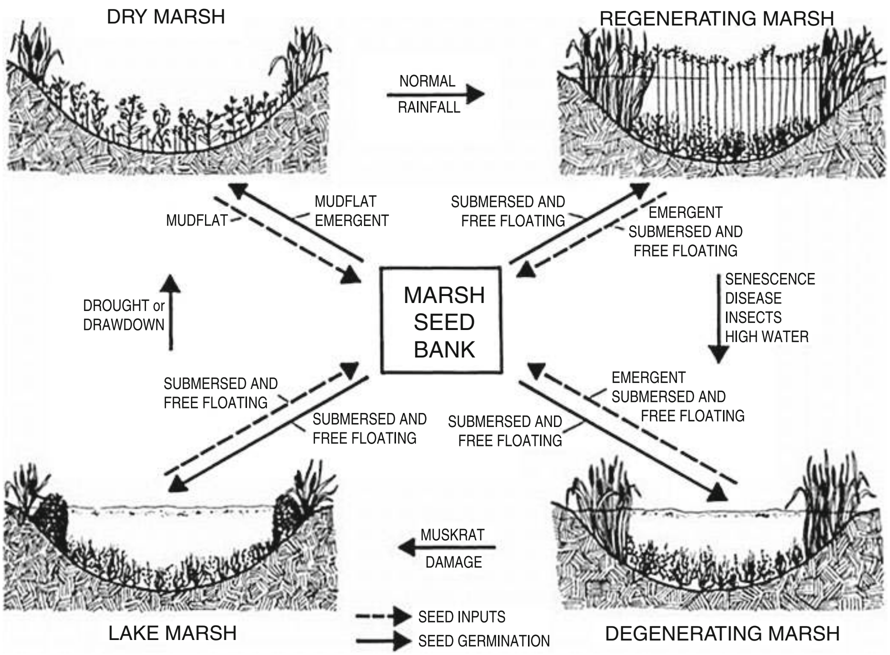

Fig. 1 Changes in vegetation caused by cyclical change in water levels in a prairie pothole over a period of 10–20 years typically (van der Valk 2012)

Many models using some variant of the vital attribute approach have been developed to predict changes in the composition of wetland vegetation after a major disturbance (fire, flooding, drawdown). See van der Valk (2007) for a description of several of these models.

As noted, a vital attribute model for wetlands was first developed to describe and predict changes in the composition of emergent vegetation in prairie potholes caused by alternating years of above normal and below normal annual precipitation (Fig. 1). During such a "wet-dry" cycle, the emergent vegetation of potholes is nearly eliminated by two or more years of high water. The emergent vegetation, however, cannot become re-established from seed until the next dry period when the pothole is largely or entirely free of standing water. For vital attributes to be useful for understanding and predicting vegetation changes, they have to be linked to changes in environmental conditions.

Environmental Sieve Models

In vital attribute models, the environment acts as a "sieve" that determines which species can become established and which will persist under specific environmental conditions (Fig. 2). Whenever the characteristics (state) of the environmental sieve changes, the species composition of the impacted community is altered because

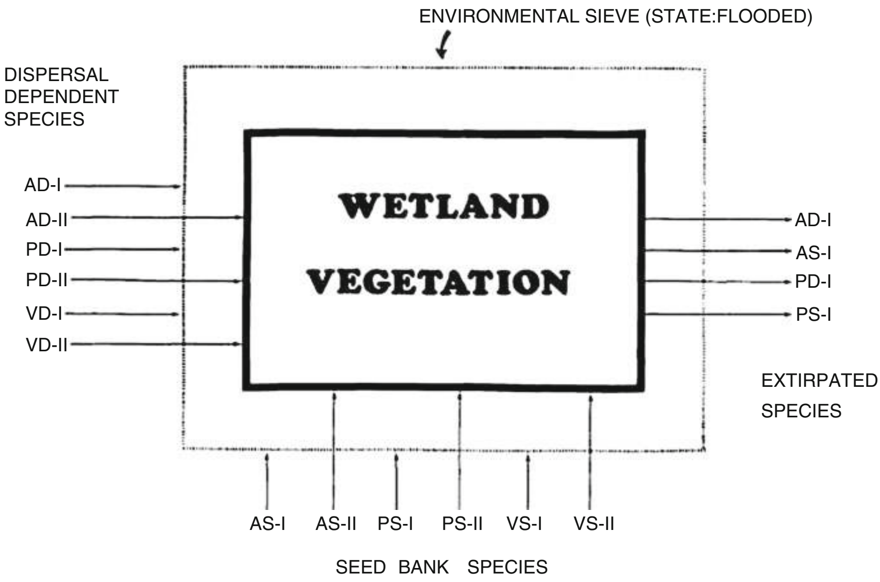

Fig. 2 Environmental sieve model of succession. The species composition of a wetland changes if the state of the environmental sieve changes from flooded (illustrated) to drawdown. The various types of species (AD-I, AS-I, AD-II, etc.) defined by their vital attributes are described in the text (From van der Valk 2012)

established species are eliminated and new species become established. For example, in Fig. 2, when the sieve is in the flooded state, species with some combinations of vital attributes cannot become established (AD-I, AS-I, PD-I, PS-I, VS-I, and VS-I) because their seed cannot germinate under water, but others can (AD-II, AS-II, PD-II, PS-II, VS-II, and VD-II). When the environmental sieve is in this state, most annuals (AS-I species and AD-I) and short-lived perennials (PS-I and PD-I species) will be eliminated from the pothole after a couple of years of flooding because they reach the end of their life expectancies and they cannot become re-established from seed. High water may also result in an expansion of populations of muskrats (*Ondatra zibethicus*). They can destroy most of the remaining emergent vegetation because of their lodge building and feeding activities. When the wetland has no standing water during drought periods, species that were eliminated during flooded periods become re-established from seed.

The most rigorous test of this modeling approach to predicting changes in wetland vegetation was a 10-year long experimental study done in the Delta Marsh, Manitoba, Canada. In this study, ten large experimental cells were constructed in the Marsh and water levels were manipulated using pumps to reproduce previously observed changes water levels over a wet-dry cycle in this wetland. Water levels in each cell were (1) raised for two years to one meter over mean water levels to simulate historic high water years; (2) then lowered to 0.5 m below normal for one or two years to simulate drawdown conditions; and (3) finally raised to

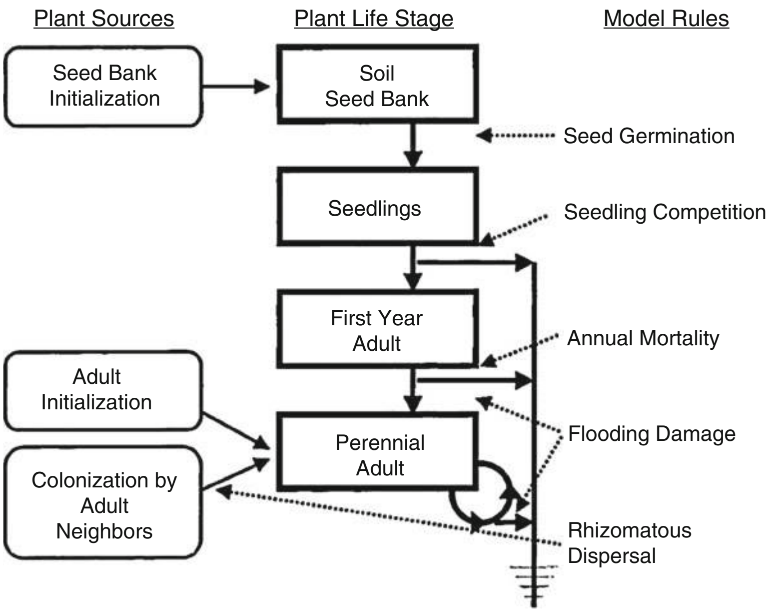

Fig. 3 A vital attribute/environmental sieve model of the dominant emergent species of the Delta Marsh, Manitoba, Canada (From van der Valk 2012)

various depths for 5 years. Seabloom et al. (2001) developed a model based on vital attributes of the dominant species and how changes in water levels affected the survival, recruitment, and location in each cell of each of the dominant emergent species (Fig. 3). This model was developed using vital attribute information gleaned from studies done previously on other prairie wetlands. A detailed description of this study, called the Marsh Ecology Research Program (MERP), can be found in Murkin et al. (2000).

A comparison of the actual vegetation found in the MERP cells and that predicted by the model was used to test the accuracy of the model (Seabloom et al. 2001). Figure 4 illustrates the mean predicted and actual percent of the cells covered by one of the dominant emergent species, *Phragmites australis*, over the course of the study. The model predicted the observed decline of *Phragmites* during the 2 years (1981, 1982) that the cells were flooded to one meter above normal. It also predicted that *Phragmites* would be much more abundant (>20%) in the cells during the drawdown years (1983, 1984 in Fig. 4) than was the case (ca. 10%). *Phragmites* seed germination was lower than predicted during the drawdown. During the reflooding years, the model predicted that the percent of a cell covered with *Phragmites* would initially be high (ca. 20%) during the first couple of years (1985, 1986) and then would decline for the last 3 years. In reality, the percent of a cell covered by *Phragmites* during the reflooding years was initially lower than predicted. After 1986, however, the model and predicted percent coverage were fairly close and had a similar pattern (Fig. 4).

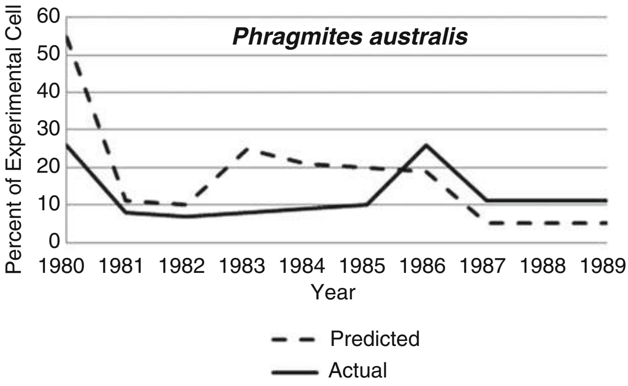

Fig. 4 Mean predicted and actual percent of a cell covered by *Phragmites australis* in the MERP complex. The cells were flooded to 1 m above normal in 1981 and 1982; drawndown in 1983 and 1984; and reflooded from 1985 to 1989. Actual percentages of *Phragmites* in the cells were estimated from low-level aerial photographs (Adapted from Seabloom et al. 2001)

The reason for the discrepancies between the predicted and actual percentages of a cell covered with *Phragmites* varied depending on the state of the environmental sieve. During the drawdown, seed germination was not as high as predicted. The reason for this discrepancy is unknown, but it is clear that more detailed information about the seed germination requirements of *Phragmites* needs to be incorporated into the model. The seed germination of the dominant emergent species in the Delta Marsh is known to be affected by temperature, soil moisture, and salinity (van der Valk 2007). Interactions among emergent species were evident in the field, especially preemption. *Phragmites* was not able to expand into some areas with optimal water depths until other species that became established in these areas began to die back. Preemption effects on the establishment and spread of emergent species were not part of the model and need to be added to increase its accuracy.

Future Challenges

Over the years, many difficulties with the application of the vital attribute/environmental sieve models for predicting changes in the composition of vegetation have been noted. These include: (1) uncertainties about which species are in the regional species pool due to the introduction or invasion of new species and recent local extinction of species; (2) uncertainties about the dispersal potential for most species to a given site; (3) uncertainties about the environmental conditions under which species can become established from seed at a given site; (4) uncertainties about pre-emption or priority effects, i.e., the order in which species arrive; and (5) uncertainties about the consequences of species interactions (competition, allelopathy, herbivory, etc.). Many studies suggest that variation in seed germination rates, priority effects, the vagaries of dispersal, and establishment of new invasive species can have major impacts on community composition (Toth and van der Valk 2012; van der Valk 2012). These problems do not invalidate this approach, but they do indicate that, to increase the accuracy of this class of models, additional life-history attributes may have to be added as abiotic and biotic conditions change over time at a site and as new species become established in a region.

Egler's $10,000 Succession Challenge

4

John Anderson

Contents

Abstract

Frank Egler was a proponent of a variant of Gleasonian succession called "initial floristics," which suggests that the early establishment of plant species has a great influence on later vegetation succession. In contrast, Clementsian succession suggests that vegetation progresses in stages to a climax. Historically, this idea has been widely held by teachers and managers, but Egler did not observe this type of succession. Egler offered a $10,000 reward for anyone who could give an example of vegetation stages progressing to a climax stage in support of Clementsian succession. No one has successfully challenged Egler's concept. Initial floristics as a variant of Gleasonian succession has withstood many decades of scrutiny.

Introduction

Frank Edwin Egler, Ph.D., was an eminent plant ecologist and conservationist in his time. Born April 26, 1911, in Manhattan, NY, he was drawn to nature and analytical thinking. As a college student, he studied under such noted ecologists as Henry Cowles (Chicago), William Skinner Cooper (Minnesota), and George Nichols (Yale). He earned his Ph.D. from Yale University in 1936 and went on to publish over 400 papers and five books. He eventually made his home on his family's summer home in Norfolk, Connecticut, which came to be known as Aton Forest. By the continual acquisition of adjacent properties, Egler eventually amassed over 1,100 acres of forest lands, old fields, and wetlands, mostly kept as a natural area (as free as possible from human interference). These lands were his base of operations and his inspiration, on which he conducted much of his research, especially applied ecological vegetation management. Egler died on December 26, 1996. He left his estate to a nonprofit conservation organization that he founded called Aton Forest, Inc. The property continues to be owned and managed by Aton Forest, Inc.; its mission is to carry on Egler's legacy of scientific research and conservation activities.

Ecological Theories

Early on Egler found himself in a controversy over the ecological theories of plant ecology. Fredric Clement proposed the dynamic ecology concept (see Allred and Clements 1949), which came to be known as plant succession to climax, where discrete plant communities not only succeed one another in a deterministic way but each proceeding stage preparing the way for the next stage. The final stage would vary with climate, but would be stable, i.e., the climax. Henry Gleason proposed the individualistic concept (Gleason 1926), where individual species associate with one another to form communities, a low degree of holistic integration, but in a nondeterministic way. Egler proposed a variant on Gleason's individualistic concept, which was called initial floristic composition (Egler 1954), where early establishment of plant species had a great influence (barring external effects of, e.g., fire, flood on the future development of succeeding plant communities). During his life, Egler repeatedly pointed out that the title of his paper was Initial Floristic Composition: *a factor* in old-field vegetation development. In this paper, he renames Clement's plant succession concept as Relay Floristics and acknowledges that it does play a role in vegetation development, but is not the sole or even the most important factor.

As Egler developed his ecological and vegetation insights into applied science and specifically right-of-way vegetation management, the importance of this distinction of concepts came to light. The assumption, for example, that a shrub community is the natural and necessary stage to proceed a pioneer forest type would naturally influence management decisions. From this perspective, shrubs pave the way for trees, so it would be logical to get rid of the shrubs if you do not want trees. If initial floristic composition is more important, then eliminating trees early on should prevent a future forest if the shrub community resists rather than encourages new tree invasion. Egler spent much of his professional life investigating and demonstrating these ideas. He was vexed that so often he came up against the belief in a succession to climax theory from land and vegetation managers and students and teachers, despite the fact that Clement's concept had lost favor or been discounted by ecologists.

Egler's Challenge

With the publication of his two-volume book *The Plight of the Right of way Domain: Victim of Vandalism* (Egler 1975), Egler printed in its appendix his $10,000 Challenge (p. 283). Here he offers a reward for any ecologist who can scientifically prove the cause and effect relationship of Clementsian Relay Floristics through at least five stages of development over a minimum of 25 years with evidence to be judged by a panel of noted ecologists. No one ever took him up on this offer. Egler did speak about being referred to someone in Ohio who was managing vegetation where tree invasion into dense shrub stands was common. He contacted the person and went to Ohio to see the site and discuss its history and the observations that had been made. He was told, yes, trees were very commonly growing up through the shrub canopy, and after some further questioning, he was told, "But I don't know which are older, the shrubs or the trees." This, of course, is the essence of the whole argument!

So the Challenge stands unchallenged. Many foresters and right-of-way vegetation managers now acknowledge the significance of Egler's ideas to their planning and work, though full understanding and implementation of his concepts and management practices is yet to be realized.

David J. Gibson and Beth A. Middleton

Contents

Abstract

As complex and dynamic systems, wetlands offer the opportunity to investigate and incorporate the ecological concept of succession in educational settings. For example, the well-known, classic hydrosere concept is illustrated in numerous ecology and life-science textbooks. In this chapter, the drawbacks of using the hydrosere successional concept are assessed, and two examples of using wetlands to illustrate the process of succession for educational purposes are described. In each case, the premise and approach is that students best "learn ecology by doing ecology."

Introduction

As complex and dynamic systems, wetlands offer the opportunity to investigate and incorporate the ecological concept of succession in educational settings. For example, the well-known, classic hydrosere concept is illustrated in numerous ecology and life-science textbooks. In this article, the drawbacks of using the hydrosere successional concept are assessed, and two examples of using wetlands to illustrate the process of succession for educational purposes are described. In each case, the premise and approach is that students best "learn ecology by doing ecology" (Gibson et al. 1999).

Be Careful Using the Classic Hydrosere Succession Concept as a Teaching Tool

The classic hydrosere model of succession, where infilling of a lake or pond through time leads to a "climax" forest community, has a long history and is reproduced in many textbooks as a good example to teach the concepts of primary succession. However, numerous exceptions to this classic sequence of hydrosere succession have been observed, and forest communities often do not represent a final, stable community. Infilling of basins with organic matter does occur (i.e., terrestrialization), but succession is rarely unidirectional, and does not result in mature upland or mesic "climax" forests replacing earlier successional bog stages (Klinger 1996). Instead, for understanding wetland succession, a Gleasonian approach based upon species life histories is more appropriate (Van der Valk 1981; Middleton 1999). The fallacy of using the Clementsian model in teaching successional concepts was outlined by Gibson (1996) who advocated a more probabilistic, hierarchical approach.

The Olentangy River Wetland Research Park and EARTH University's Tropical Wetland Project

Two riverine wetlands constructed by William Mitsch and colleagues at Ohio State University provide examples of ecosystem-scale systems that can be used for conservation education and research in a successional wetland setting (Mitsch et al. 2008; Mitsch et al. 2012). The Olentangy River Wetland Research Park (ORWRP) is a pair of 1 ha flow-through-created riverine wetland basins established in 1994. One basin was planted with 13 native species of macrophytes; the other was unplanted and allowed to colonize naturally (Mitsch et al. 2012). After 15 years, the planted basin had higher plant community diversity and lower primary production than the unplanted basin. In addition to monitoring vegetation, soil development, water quality changes, and carbon and nitrogen dynamics, the faculty at The Ohio State University developed at least 35 courses taking advantage of the successional dynamics at the ORWRP (http://swamp.osu.edu/Academics/academic_courses.html). Similarly, a swamp palm (*Raphia taedigera*

Mart.) forest in La Reserva Wetland at EARTH University, Costa Rica, is one of several natural and constructed wetlands (112 ha in size), which has been developed as a campus research wetland since 2005 (Mitsch et al. 2008). In addition to improving effluent water quality of an animal farm, dairy plant, landfill, and banana plantation, studies on these wetlands have been integrated into the educational curriculum at EARTH University for over 14 years. As the constructed wetlands change in plant composition and structure over time, they offer opportunities to teach successional theory.

Integrating Wetland Succession into Undergraduate Life Science Courses

To incorporate the "learning ecology by doing ecology" concept, a set of experimental plots were established in a postagricultural bottomland forest in southern Illinois (Gibson et al. 1999, 2005) (Fig. 1). Mowing and rototilling, fertilizer addition, and herbivore exclusion treatments allowed a test of the effects of disturbance as defined by mowing and rototilling, and deer browsing and resource availability on secondary succession in this wetland habitat (Mathis 2001). One hundred and forty-four 5 × 5 m plots in 16 15 × 15 m blocks were established

Fig. 1 Aerial view of experimental research plots in a postagricultural bottomland habitat in southern Illinois. The plots contrasted mowing and fertilizer treatments. Twelve of the 16 blocks excluded large herbivores. Undergraduate ecology laboratory classes tested the initial- versus relay-floristics models. Each of the square blocks is 15 × 15 m and contained nine 5 × 5 m plots assigned to mowing (control, mowed annually, mowed and rototilled annually) and fertilizer (control, fertilizer every 5 years, and annual fertilizer application) treatments (Photo by David Gibson)

Fig. 2 Undergraduate students counting tree seedlings in the bottomland hardwood forest secondary succession plots (Photo by D. J. Gibson)

following plowing of the abandoned agricultural field in 1996, with experimental treatments and data collection maintained through 2002 (http://www.plantbiology.siu.edu/long-term/). A second set of plots with similar mowing and fertilizer treatments, but without herbivore exclusion, were established during the same time period in a nearby upland area (Gibson et al. 2005).

These plots were used as a context for inquiry-based undergraduate ecology laboratories to test the basic tenets of succession, including an evaluation of relay versus initial floristics, seedling growth experiments (Barko et al. 2004), and predator-prey relationships (Oyler et al. 1999), and for individual undergraduate research projects (Rice et al. 1999). Such plots could also be used for teacher training of inquiry methods for K-12 education. Evaluations showed that these laboratories were educationally effective in meeting our objectives (Bhattacharyya 1999).

Undergraduates were able to test relay versus initial floristics (i.e., contrasting sequential versus early species establishment) in these plots by noting the number of trees established in disturbed (mowed) versus undisturbed (unmowed control) plots (Fig. 2). Before collecting these data, students were asked to conduct a preproject assessment consisting of a multiple choice sentence stem and a concept map (Box 1) to evaluate their knowledge of succession prior to the exercise. After collecting data on tree density, the students were asked to repeat the assessment in light of the data that they had collected and their field experience (Fig. 3). After this field exercise, the students were introduced to the concepts of relay versus initial floristics and generally found that their observations supported the latter and that their knowledge and understanding of succession had improved (Bhattacharyya 1999).

Box 1 Pre- and Postproject Assessment

Student demonstrates their understanding of the concepts related to succession after the field exercise by completing the sentence stem (1) or drawing a concept map (2) as directed below.

1. Sentence Stem:

   Circle one of the following.
   After the farmer stops cultivating a field, trees come into abandoned fields: 25 years, 10 years, 3 years, 1 year, right away.

2. Concept Map:

   Draw a concept map of succession including the following terms (plus additional terms you think are necessary):
   Plant types: tree seeds, tree seedlings, grass seeds, grass seedlings, mature forest
   Changes: cutting, mowing, dispersal

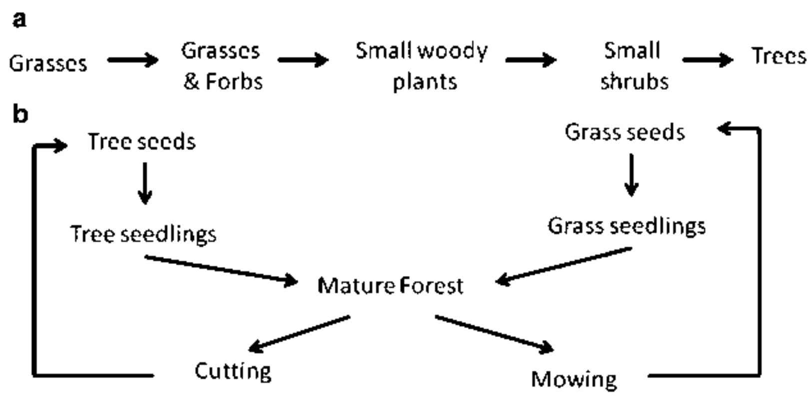

Fig. 3 Sample of student's concept maps illustrating their understanding of the process of secondary succession in bottomland hardwood forest. a) Low-scoring concept map, b) high-scoring concept map (Redrawn from Bhattacharyya 1999)

Future Challenges

Successional wetlands provide a setting to place educational opportunities into current ecological theory. However, it is necessary to avoid Clementsian successional ideas in which a predictable sequence of species changes leads to a "climax" community. There are limitations and caveats for using space-for-time substitutions (i.e., chronosequences where sites of different times since disturbance are compared instead of following a site continuously through time since disturbance) (Neiring 1994; Johnson and Miyanishi 2008; Walker et al. 2010) and spatial belting within wetlands as representations of temporal succession (Neiring 1987). Successional wetlands allow field-based laboratory classes to be developed based on using inquiry-based learning. This pedagogical approach can also be used to alleviate negative adult perceptions of these habitats that arise from the view that they are undesirable, dangerous places (Anderson and Moss 1993).

In addition to the examples cited here, some online education sources focused on using wetland systems are provided in Box 2.

Self-Design vs. Designer Theories and Wetland Restoration and Creation

6

Arnold van der Valk

Contents

Abstract

Wetland restoration and succession are essentially attempts to accelerate and direct succession. However, competing theories about the nature of succession exist. One theory developed by F. E. Clements postulated that all the vegetation in an area would eventually reach a final, stable stage that he called the climax. This deterministic succession theory, now called the self-design theory, has been adopted in numerous restoration/creation projects. It implies that environmental conditions are the main determinant of the vegetation that develops. An alternative theory of succession, associated with H. A. Gleason, emphasizes that the characteristics of each plant species (e.g., seed dispersal potential) and contingent environmental factors (e.g., disturbances) have a major influence on the composition of the vegetation that develops and that there is no fixed end point. This individualistic theory of succession in the restoration field is known as the designer theory. Most plant ecologists today are advocates of the designer theory.

Introduction

When it comes to the restoration/creation of wetlands, it is widely assumed that it is possible to establish vegetation in them that closely resembles that of some target wetland, all else being equal. This is one of the underlying assumptions of wetland mitigation policy in the United States and elsewhere. Because wetland restoration/creation is essentially accelerated succession, the extensive literature on succession provides both theoretical concepts for designing and practical guidelines for executing restoration/creation projects. Consequently, the need to apply succession theory to aid in the design of restoration/creation projects has been frequently advocated. However, for this to be effective and successful, it is necessary to use up-to-date successional theory.

Pickett et al. (2011) compare and contrast classical and contemporary theories of succession. The classical theory, developed primarily by Frederic E. Clements in the early part of the twentieth century, was a deterministic theory that postulated that all the vegetation in a given area would eventually reach a climax. This climax vegetation would be a stable assemblage of species that was in equilibrium with the regional climate. Interactions of species on a site during succession (primarily competition) plus changes in environmental conditions caused by the plants themselves, called reactions (e.g., increased soil organic matter and available nutrients), caused changes in species composition over time until environmental conditions stabilized and the plant species were in competitive equilibrium. In the classical theory, it is the climate that is the major determinate of the type of climax vegetation that develops because only the species best adapted to this climate will ultimately survive. Nevertheless, the classical theory recognized that succession on any given site within a region was affected by site conditions (soil moisture, soil nutrients, local disturbances, herbivores, etc.), limitations on species dispersal to the site, and the performance (seed germination, seedling survival) of species that reached the site. One or more of these factors sometimes prevented the development of the expected climax vegetation.

The contemporary theory of succession, which was formulated in the last half of the twentieth century, differs from the classical theory primarily in its emphasis on the importance of contingent factors (disturbances, site conditions, vagaries of seed dispersal, etc.) for determining whether a given species is found or not on a site at a given time. In the last 60 years, numerous studies of succession have demonstrated that in a given area it is largely driven by contingent factors. Consequently, succession does not have a fixed trajectory or outcome, and many different vegetation types could potentially become established on the same site. Rather than being deterministic, succession is viewed as a probabilistic process.

Self-Design and Designer Theory

Although the terminology is different, in the wetland restoration literature two different successional theories have been proposed, self-design and designer, to guide efforts in vegetating newly restored or created wetlands (Mitsch and

Wilson 1996). One of the earliest proponents of the self-design concept was Howard T. Odum. Odum, however, called it self-organization (Odum 1988). Odum believed that if an area was "seeded" with suitable organisms that, as a result of their differential survival and interactions (feedbacks) among them, self-organization would result in development of the most energy efficient ecosystem under a given set of environmental conditions. Like the classical theory of succession, of which it is a variant, self-organization is a deterministic process with a fixed endpoint. For Odum, the climax ecosystem operates at optimal efficiency, and less energy efficient ecosystems will be replaced by more energy efficient ones. See Månsson and McGlade (1993) for a critique of Odum's concepts. One of Howard Odum's students, William J. Mitsch, applied Odum's self-organization/self-design concept to the restoration/creation of wetlands (Mitsch and Wilson 1996). As was the case with Odum, self-design involves introducing propagules of as many species as possible and letting "natural forces" choose the most appropriate species. Again, it is classical succession theory under another name.

The designer approach is described by Mitsch and Wilson as "introducing species and expecting their survival in Gleasonian zones, akin to gardening and landscape architecture." The designer theory is a variant of the contemporary theory of succession. There is no fixed endpoint, and, within the constraints imposed by environmental conditions, many different kinds of vegetation could be established in a restored or created wetland because it is possible to manipulate the species composition of the initial vegetation (e.g., using different seed mixes) and to manipulate environmental conditions to favor some species over others. In other words, it is possible to direct succession to obtain a desired vegetation type.

As pointed out by van der Valk (1998), the self-design concept has two important implications: (1) it suggests that it easy to establish vegetation – it only requires introducing suitable propagules; and (2) because of self-design, the type of vegetation that develops is inevitable and cannot be altered. Thus, according to the self-design theory, if the vegetation that develops is composed mostly of weedy species and does not resemble that in target wetlands, there is nothing that can be done to prevent this. On the other hand, the designer theory implies that the role of restoration ecologist is much more than just a sower of seeds. In order to establish to establish a particular kind of vegetation, it is necessary to have detailed knowledge of the life-history attributes of the species: how species are dispersed, under what conditions they can become established, what is their life expectancy, what are the main sources of mortality, etc. In fact, restoration ecologists have demonstrated repeatedly that it is possible to establish desired vegetation in restored and created wetlands if you understand the establishment and growth requirements of the constituent species. In short, self-design and designer restoration theories are not new. They are restatements, of the discredited classical theory and the contemporary theory of succession, respectively. Only the application of the contemporary succession theory to wetland restoration and creation projects will improve their outcomes.

Future Challenges

Improving the quality of wetland restoration and creation projects is essential if funding for them is to continue. For projects where self-design has been assumed to result in the establishment of suitable vegetation, the failure of the expected vegetation to develop has increasingly become an embarrassment to agencies and organizations funding these projects. Because the self-design assumption greatly reduces the cost of projects, convincing funding agencies to allocate the funds needed to establish suitable vegetation, not just suitable hydrology, is needed. Not only funding will be needed to establish suitable vegetation, it will also require developing sources of wetland seeds and plants of local provenance and effective techniques for successfully establishing suitable species where this has previously not been attempted. Fortunately, a great deal of work has been done on propagating wetland species and developing planting techniques in parts of the world where self-design has not been assumed (van der Valk 2009). The control of invasive species may also be needed to prevent them from dominating recently restored or created wetlands.

Cattle Grazing in Wetlands

7

Beth A. Middleton

Contents

Abstract

Cattle grazing drives successional change in wetland vegetation by removing tall grasses and other vegetation. As a disturbance, cattle grazing in some ways resembles natural disturbances such as native mammal grazing and lightning-strike fire, which can support higher biodiversity in wetlands. To encourage rare and Red-Listed species, natural land managers sometimes incorporate a variety of techniques to remove tall vegetation including mowing, hand-cutting, burning and cattle grazing. As a farming practice, cattle grazing was once very common in world wetlands, but as agriculture intensified after WWII, small-scale farmers slowly stopped grazing cattle in natural wetlands. As a result, tall macrophyte and woody species have overgrown some wetland types once used as pastures for cattle.

https://doi.org/10.1007/978-90-481-9659-3_60

Introduction

Cattle grazing is a disturbance, which can alter the successional dynamics of wetlands (Fig. 1; Middleton 1999). This change in species composition is caused by the cattle because they create openings in the dominant vegetation, soil disturbances (hoof prints, lounging, manure, cattle paths), swim tracks, alien species invasion, interference with native animal species, and sometimes salt water intrusion (Finlayson and Von Oertson 1993; Fig. 2). Most wetlands can recover from grazing, even though the species composition of the wetland may be changed permanently.

How Cattle Change Wetlands

Heavy cattle grazing damages natural wetland vegetation more than lighter grazing (Middleton et al. 2006). During times of grazing, the cattle promote the spread of shrubs by creating invasion opportunities in otherwise dense vegetation and dispersing shrub seeds via manure. If the cattle are removed, the shrubs may mature and come to dominate the wetland (Fig. 3).

The restoration of wetlands damaged by cattle grazing can be difficult. If shrubs invade after cattle grazing, these can be difficult to remove because of their deep roots (Fig. 4). Stream banks may need costly rehabilitation after cattle grazing. Cattle damage stream banks in their pursuit of water in stream beds.

Historically, hay in wetlands was cut to feed to cattle in North America, Europe, Asia, Africa, and India. These wetlands included northern peatlands, salt marshes,

floating freshwater marshes, and monsoonal wetlands (Middleton 1999). In North America and Europe, these labor-intensive farming practices were discontinued gradually after World War II (Middleton et al. 2006). Recently, to preserve the high biodiversity of wetland vegetation in Europe and elsewhere, wetland vegetation is managed to curtail the growth of tall plants.

Cessation of Cattle Grazing in World Wetlands

Agriculture around the world has become more industrialized around the world since WWII, so that marginal land has been abandoned (Benayas et al. 2007). At the same time, cattle grazing in natural areas has stopped in many regions of the world (Middleton et al. 2006), so that a loss of biodiversity has occurred in adjacent natural ecosystems (Benayas et al. 2007). The loss of biodiversity occurs as taller vegetation such as shrubs or macrophytes overtops shorter vegetation (Middleton et al. 2006).

The reasons for the exodus of people from rural areas is mainly socioeconomic factors, including dwindling resources for small farmers with farm industrialization, but also better opportunities in the city than in the countryside (Benayas et al. 2007). Also, many rural people left the country after the collapse of the former Soviet Union (Baumann et al. 2011). Other historical occurrences have caused declines in the farm population, resulting in landscape-level changes in the countryside. After the

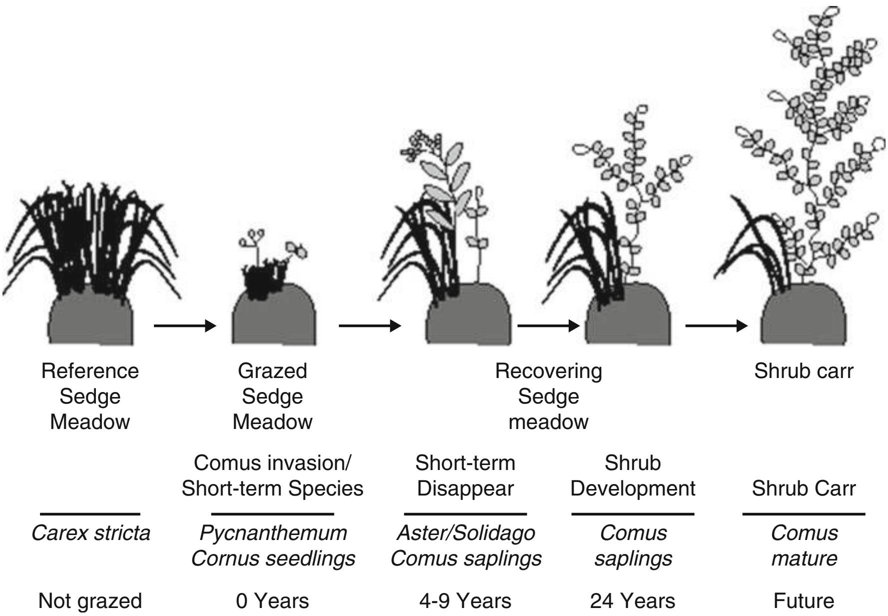

Fig. 3 Cattle grazing damages sedge tussocks in northern sedge meadows and the damage allows an invasion pathway for shrubby species such as red osier dogwood (*Cornus sericea*). Shrubs are browsed by cattle, so that the sedge meadow may not appear changed while cattle still graze the wetland. In the years immediately following cattle grazing, the shrubs mature and eventually dominate formerly grazed sedge meadows. In certain northern peatlands, the formation of a shrub carr is not an inevitable product of succession, but instead often is facilitated by cattle grazing

Eurasian plague of AD 1347, shrubs proliferated as pastures were abandoned in Europe with fewer people to tend the cattle (Yeloff and Van Geel 2007). Large-scale socioeconomic changes in the rural countryside have other impacts on surrounding wetlands and their biodiversity (following Benayas et al. 2007).

Future Challenges

Small-scale farmers have stopped grazing cattle in many natural areas around the world, and this land-use change has caused a crisis in land management in wetlands. In many types of wetlands, the spread of unwanted macrophytes and woody species has occurred on formerly pastured wetlands, resulting in the loss of rare and Red-Listed species (Middleton et al. 2006). One challenge for land managers is to find ways to maintain the biodiversity of these wetlands following these rural land-use shifts. Managers have incorporated various strategies to control tall vegetation including mowing, hand-cutting, burning, large mammal grazing, and even the

Fig. 4 The removal of woody species from former grazing areas is difficult and labor intensive. Cattle eat and spread the seeds of mesquite (*Prosopis juliflora*) in the Keoladeo National Park (India) (Photo by Beth Middleton)

reintroduction of cattle (Middleton et al. 2006). In mountain grasslands, management to restore species from seed banks and other sources by mowing still has some benefits for reestablishing biodiversity even after 20 years of cattle grazing abandonment (Galvánek and Lepŝ 2008).

Fire in Borneo Peatlands

8

Sue Page and Agata Hoscilo

Contents

Abstract

Fire frequency has been increasing in recent decades in Southeast Asia, particularly with the expansion of agriculture and wood extraction on the islands of Borneo and Sumatra. These peatland fires are causing high emissions of carbon and particulates, as well as long-term changes to forest composition, biomass, and structure. Only a few tree species in this ecosystem have fire adaptations, e.g., tumeh (*Combretocarpus rotundatus*), so that such species are common on fire-degraded peatlands. The protection of remaining forests on the islands of Borneo and Sumatra could be possible as a result of policy initiatives to reduce greenhouse gas emissions. In addition, rehabilitation of these forests may present opportunities for mitigation. At the same time, there are a number of technological and sociological challenges for the restoration of these forested peatlands. These landscapes are now highly fire-prone, and the livelihoods of local people need attention for these measures to succeed.

Introduction

Fire is presently the most important disturbance affecting vegetation cover at a global scale, with an estimated 6 million km^2 affected on an annual basis (Mouillot and Field 2005). The largest increase in regional fire activity is currently occurring in the humid tropics, particularly in the rainforests of Southeast Asia and South America. Before recent times, fire activity was both infrequent and atypical of these tropical forest environments, but now wildfires are increasing rapidly, resulting in extensive forest loss and degradation and a wide range of environmental, social, and economic impacts (Cochrane 2006).

In recent decades, the Southeast Asia region has experienced extreme rates of forest loss, degradation, and wildfire (Achard et al. 2002; Langner et al. 2007; Hansen et al. 2009). During the period 1950–2000, 40% of Indonesian forests were cleared, with agricultural expansion and wood extraction identified as the main drivers of forest loss (Geist and Lambin 2002). Both activities have also increased the risk of forest fire. Langner and Siegert (2009) demonstrated that around 21% of land in Borneo was subject to fires during 1997–2006, with 6.1% (45,000 km^2) of the forest affected by multiple fires, most if not all of which were anthropogenic in origin. Some of the most extensive fires since the mid-1990s have occurred in this region's peat swamp forests, particularly on the islands of Borneo and Sumatra (Langner et al. 2007; Langner and Siegert 2009). In 2002, for example, 73% of the fire-affected forest area of Borneo was peat swamp forest and in 2005, it was 55% (Langner et al. 2007) (Fig. 1).

Tropical peatland, which supports a natural vegetation cover of peat swamp forest, covers 250,000 km^2 of the coastal lowlands of Southeast Asia (Page et al. 2011) and is characterized by the presence of very thick peat deposits often exceeding depths of 10 m or more. In undisturbed peat swamp forest, peat accumulation is maintained by a strong interrelation between the forest vegetation and the peat under anoxic, waterlogged, nutrient-poor conditions, which reduce the rate of decomposition enabling organic matter derived from forest biomass to accumulate on the land surface. Peat swamp forest contains a diverse range of tree species, many of them commercially valuable for timber or other uses, while the forest and underlying peat are important for carbon storage, with approximately 100–150 t C ha^{-1} stored in the forest biomass and 2775 t C ha^{-1} in the peat (assuming an average peat thickness of 5.5 m) (Page et al. 2011).

Over recent decades, very large areas of peat swamp forest in Southeast Asia, especially in Indonesia and Malaysia, have been deforested and drained to make way for large-scale industrial plantations of oil palm and pulpwood (*Acacia*), and for smallholder agriculture (Miettinen et al. 2011). Many plantation companies, particularly in Indonesia, have employed fire as a cheap and rapid land clearance tool to dispose of

Fig. 1 Peat swamp forest recovering from a single fire in 1997 in southern Central Kalimantan, Indonesian Borneo; after 9 years of regrowth, the woody biomass had reached around 10–15% of the biomass in primary peat swamp forest (Photo taken by A. Hoscilo in 2006)

logging residues, while smallholders have used fire to keep their land clear of invasive vegetation. The risk of wildfire on peatland has been increased considerably by recent forest disturbance and drainage activities (Langner and Siegert 2009). In the past, small scale wildfires escaping from agricultural land would have quickly burnt-out in the humid and waterlogged peat swamp environment, but the combination of forest disturbance and drainage have allowed peatland fires to run out of control, destroying both the forest vegetation and burning away the dry surface of the peat (Page et al. 2002). This has resulted in large carbon emissions to the atmosphere as well as a wide range of other detrimental environmental impacts.

Environmental Impacts of Tropical Peatland Fires

Tropical peatland fires make a substantial contribution to the global burden of greenhouse gases (Bowman et al. 2009) and the devastating peatland fires of 1997–1998 in Indonesia were one of the largest peak emissions events in the recorded history of fire in Southeast Asia, if not globally (Schultz et al. 2008; van der Werf et al. 2006). Page et al. (2002) conservatively estimated that these fires released more than 870 Mt of carbon to the atmosphere, which was equivalent to

14% of the average global annual fossil fuel emissions released during the 1990s. In contrast to forests on mineral soils, combustion losses from belowground (i.e., peat) carbon stocks in peat swamp forest fires can be much greater than the losses from surface and canopy fires, which consume only the aboveground biomass. In addition, the smoldering nature of peatland ground fires (i.e., fires which burn below the peat surface in a low oxygen environment) results not only in the release of greenhouse gases (CO_2, CO and CH_4) but also fine particulates and a range of volatile organic compounds. The resulting dense pall of smoke can affect the whole region and result in a wide range of human health problems (Heil and Goldammer 2001).

The most extensive peatland fires of the last two decades have occurred during ENSO events, when the relatively short dry season affecting the western part of the Southeast Asia region is extended, from 2 or 3 months to up to 6 months or longer. While ENSO may provide suitable dry weather conditions, most of the region's uncontrolled fires are fostered and propagated by the increased fire susceptibility of over-drained peatlands. This problem is demonstrated by a study of the fire regime in the former Mega Rice Project (MRP) area on peatland in southern Central Kalimantan (Hoscilo et al. 2011). Over a 23 year period (1973–1996) prior to peatland drainage in the mid-1990s, fires affected 23% of a 4,500 km^2study area, with most fires located along the forest edge, i.e., in disturbed forest in close proximity to human settlements. More remote, intact forests were unaffected by fire, even during extended ENSO droughts. This situation changed markedly in the next decade. Following construction of an extensive canal network in 1995–1996 to drain the peatland for agricultural use, fires during the ENSO year of 1997 affected about 33% of the area, i.e., 10% more than had burned during the previous 23 year period. In total, more than half of the area burnt during 1997–2005, with many locations experiencing multiple fires. This rapid increase in burned area was a consequence of deforestation, peatland drainage, and increased human access; drainage and forest disturbance increased the fire risk, whilst people provided the fire ignition source.

In addition to high emissions of carbon and particulates to the atmosphere, peatland fires also result in long-term changes to the species composition, biomass, and structure of the peat swamp forest and, particularly in the case of repeated fires, greatly reduced rates of post-disturbance vegetation recovery. Peat swamp forest trees are not fire-adapted; most are thin barked, so post-fire tree mortality is high. In addition, many trees fall once the supporting peat around their root systems has burnt away. In a study of the post-fire vegetation response in Central Kalimantan, Page et al. (2009) and Hoscilo et al. (2011, 2013) have shown that peat swamp forest subject to a single, low intensity fire can undergo relatively rapid recovery to secondary forest, achieving a biomass equivalent to about 10% of that of the undisturbed forest over a 9 year period. Following multiple fires, however, the species richness and density of trees, saplings and seedlings within secondary vegetation are greatly reduced, which decreases the capacity of the vegetation to recover naturally. Fire damaged peat has diminished seed availability and dispersal is impaired, leading to a decline in seedlings and saplings. Fire also removes the vegetative regeneration potential of tree bases and roots, which are burned away. Intact peat swamp forest can usually support more than 100 tree species per hectare,

Fig. 2 The most advanced stage of vegetation regrowth following a low severity second fire (burnt in 1997 and 2002). The woody regrowth is dominated by the tree C*ombretocarpus rotundatus* (Photo taken by A. Hoscilo in 2006 – four years after the last fire)

while areas affected by multiple fires are colonized by only a very small number of pioneers. In Central Kalimantan, *Combretocarpus rotundatus* (tumeh) is the dominant species on peatlands subject to several fires. Tumeh has small, winged, wind-dispersed seeds, and has adaptations, which enable it to disperse over large areas and tolerate environmental conditions in a fire-degraded ecosystem. It is a light-tolerating species, which is able to reproduce very easily both by quick production of seeds and re-sprouting from the roots. Because of these traits, tumeh spreads relatively easily into burned areas. It is also a fire-tolerating species, which can survive a second less severe fire owing to a thick bark that protects the underlying vascular tissues (Fig. 2).

At the highest levels of fire-degradation (i.e., following multiple fires), the vegetation succession back to peat swamp forest is diverted to a community dominated by ferns with very few or no pioneer trees. The dominant species of fern is usually *Stenochlaena palustris*, which can grow to heights of 1.5 m or more and its dense vegetation can overgrow and outcompete many tree seedlings and saplings in the early stages of their development. The dead and live fronds of this species are highly flammable and their presence increases the risk of future surface fires, although the low biomass of this non-woody vegetation means the fuel load is low and thus it is less likely that surface fires will generate sufficient heat to establish ground fires within the peat. Rapid colonization by non-woody vegetation may lead to the irreversible transformation of peat swamp forest into herbaceous, savanna-type habitats. A further consequence of repeated peatland fires is land subsidence, a result of peat dewatering, biological oxidation and combustion losses, which leads to an increased risk of surface flooding during the wet season. Areas burnt only once and subject to shallow, short duration flooding can undergo succession to relatively species-diverse, well-structured forest vegetation if there is a sufficiently long period without disturbance. In contrast, sites subject to multiple burns, peat subsidence and deep or prolonged

Fig. 3 Invasion of non-woody fern vegetation in locations subject to multiple fires of high severity (burnt in 1997 and 2002); the fern *Stenochlaena palustris*, growing in the foreground, is dominant (Photo taken by A. Hoscilo in 2006 - four years after the last fire)

flooding have a much more poorly developed and less diverse vegetation dominated by flood-tolerant, non-woody vegetation (Page et al. 2009) (Fig. 3).

Future Challenges

Future land use and climate changes will likely increase the frequency and severity of fires in the Southeast Asian region due largely to predict enhanced climatic seasonality, i.e., wet season precipitation increase and dry season decrease. The future behavior of ENSO is uncertain, but a recent study indicates that Indonesia as a whole could expect more frequent and longer droughts in the future (Abram et al. 2007). Deforestation itself, i.e., large-scale alterations in land cover, may also lead to more localized reductions in rainfall (Werth and Avissar 2005). These changes will be critical for the remaining fragments of peat swamp forest, which are increasingly degraded by over-logging and drainage and at considerable risk of continuing or increasing fire risk in the coming decades, unless large-scale improvements in forest management are implemented.

Opportunities to protect the remaining peat swamp forests from fire damage may come about as a result of new policy initiatives to reduce greenhouse gas emissions through avoided deforestation in developing countries (REDD and the voluntary carbon market) while the rehabilitation of degraded peatland landscapes may offer opportunities for mitigation through rewetting, fire control, and reforestation under agreements to reduce greenhouse gas emissions. Initial restoration trials in the former Mega Rice Project area in Central Kalimantan have been undertaken to investigate the effectiveness of various forms of intervention to protect the remaining carbon store (Page et al. 2009) and a REDD demonstration project, funded by the Australian Government, is underway in this area. There are many technical challenges to restoration of these ecosystems including establishing effective fire control in what are now highly fire-prone landscapes but also socioeconomic ones of persuading local people that these measures will benefit livelihoods.

Succession in Coastal Wetlands

9

John Teal

Contents

Abstract
Vegetation species and abundance in coastal marshes is controlled by salinity and immersion time. Future changes will be affected by human activities such as climate change, coastal pollution and and introduction of foreign species.

Keywords
Salinity · Phragmites · Spartina · Pollution · Climate change

Introduction

This article deals with changes in vegetation in wetlands located on coasts, subject to saline waters of the oceans.

Two factors control the species, abundance and distribution of plants occupying saltwater wetlands: salinity of the tidal water and duration of inundation – the length of time salinity stress is present. This is the water regime. The dominant species of saltwater wetlands are evolved from upland plants that developed salt tolerance and ability to survive soil anoxia, which reduces their competitive ability in other environments.

https://doi.org/10.1007/978-90-481-9659-3_2

An elegant picture of salt marsh succession was given by Alfred Redfield (1972) in his discussion of the development of Great Barnstable Marsh in Cape Cod, Massachusetts. Sediment accumulated in an inlet protected from storms until it reached about mid-tide level. *Spartina alterniflora*, which grows when flooded no more than half the time by saline water, invaded the newly created environment. This is primary succession. Succession to other species occurred when the surface elevation increased via accumulation of organic material from *Spartina* roots and rhizomes and with sediment brought in by the tides. *Spartina patens* replaced *Spartina alterniflora*, forming "high marsh." This process continued and gradually filled the inlet. As sea level rose, the marsh moved into the adjacent upland dominated by *Juncus gerardii*, black rush. Since salinity stress is reduced at elevations less frequently flooded by the tides, other plants, such as salt marsh lavender, *Limonium nashii*, sedges, and other grasses (Tiner 1987) also invaded the higher marsh. Davy (2000) gives detailed examples from Europe that involve different types of plants but show the same pattern of change as outlined by Redfield. These changes are called secondary succession.

Since salinity controls marsh plant distribution, changes in soil salinity affect succession. Soil salinity results from salinity of tidal water, frequency of flooding, rain diluting or washing salt away, and evapotransporation. Mid- and high-marsh areas that develop poor drainage can become more saline allowing more salt-tolerant species to invade and outcompete other higher plants (Bertness and Pennings 2000). In the highest marsh areas, vegetation composition is determined by frequency of tidal inundation and rain (Costa et al. 2000).

Human actions also affect salt marsh succession, a special case of autogenic succession, where humans are the biotic factor. Nitrogen pollution can shift the competitive relations of New England marsh plants allowing species to move higher in the tidal range than normal (Bertness and Pennings 2000). Shoreline development, especially if accompanied by removal of woody vegetation just landward of marshes, increases freshwater runoff and nitrogen inputs to adjacent marshes. The result is a movement of marsh zonation to higher elevations (Bertness et al. 2009). Reductions in salinity can also allow invasion of upland species. In Eastern USA, the invasive form of *Phragmites australis*, introduced from Europe in the 1950s, invades the upper edges of freshened marshes and dominates other vegetation. When combined with increased nitrogen input, the result can be a marsh vegetated by only *Phragmites* and *Spartina alterniflora* excluding all other marsh plants (Bertness et al. 2009).

Humans have modified marsh succession by introducing other species. *Spartina alterniflora*, introduced into San Francisco Bay marshes, has hybridized with the native *Spartina foliosa.* The hybrid, more vigorous than either parent, has taken over the marsh and the hybrid now occupies lower tidal elevations as well. *Spartina alterniflora*, introduced into Wallapa Bay, Washington State, has taken over mud flats and shoreline marshes (Strong and Ayres 2009). Similar changes due to introductions have occurred in Europe (Davy 2000). *Spartina* has been introduced into coastal areas in China and has increased elevations in developing marshes much as Redfield described for the USA.

Future Challenges

Future challenges are due to human actions. Climate change affects marsh succession with change in sea level and average water and air temperature. Marshes drown in the face of higher sea level and adjacent upland filled with building, roads, or commercial ports. With increased temperatures, mangroves move into temperate areas. A fivefold increase in abundance of black mangrove (*A. germinans*) from 2002 to 2009 in the Louisiana delta (Michot et al. 2010) illustrates the future marsh succession with climate warming.

Introduction

Landscapes are heterogeneous areas consisting of interacting biotic and abiotic components. Landscape ecology emphasizes landscape pattern, connectivity within the landscape, and the interaction between landscape pattern and ecological process. The interaction of people with the landscape is also an integral component of landscape ecology due to the significant reciprocal nature of the relationship between humans and the environment. Many landscape ecologists seek to apply research results to improve landscape management, conservation, and restoration. Wetland ecologists have also been applying landscape ecology principles explicitly or implicitly to answer basic questions concerning wetland landscapes and to improve wetland conservation and management. The section, *Landscape Ecology of Wetlands*, describes common landscape ecology principles and how they are being applied by wetland scientists and practitioners.

Historical Background

Landscape ecology has a relatively recent history. It was founded by Carl Troll, a German biogeographer, in the late 1930s as he sought to integrate ecology with geography to form one holistic branch of science. His effort culminated with the publication of *The Geographic Landscape and Its Investigation* in 1950. As a new discipline in Europe, landscape ecology focused on the landscape as mosaic of interacting abiotic and biotic features and also on the interaction between humans and the environment. It is through this holistic view of the environment that European landscape ecologists saw the applied sciences such as landscape management and conservation as vital to the discipline.

Landscape ecology was introduced to North America 30+ years after Troll's seminal work (Forman and Godron 1981, 1986; Risser et al. 1984). North American scientists dove into this emerging field, but rendered a slightly different form of the discipline. Rather than focusing on the applied sciences, North American scientists took a more basic and theoretical approach to landscape ecology and concentrated on spatial and temporal heterogeneity, the interaction of pattern and process, and scaling issues within the landscape. In response to these seemingly divergent paths, landscape ecologists on both sides of the world called for unification of the European and North American visions of the new emerging field of landscape ecology (Farina 2007; Wu and Hobbs 2002; Wu 2009a).

While landscape ecology was emerging as its own distinct interdisciplinary field, the principles of landscape ecology were being applied by wetland scientists and practitioners. Certainly, many of the central topics within landscape ecology were not unique to the field. In the following section, common principles and topics of landscape ecology are explained and how they are applied within the field of wetland ecology as described by section contributors is introduced.

Key Topics in Landscape Ecology

Pattern and Process

Spatial patterns across the landscape, and how processes influence and are influenced by patterns within the landscape, are a central focus of landscape ecology (Turner 1989; Turner et al. 2001). Spatial patterns describe the distribution of elements such as ecosystems, communities, species, nutrients, and water across the landscape. Processes such as species dispersal, natural disturbances, human land use, nutrient movement, and water flow influence the spatial patterns of the aforementioned landscape elements, but they are also influenced by the arrangement of the elements across the landscape. Emergent from the relationship between pattern and process are the principle topics of landscape ecology.

Spatial Heterogeneity

Landscapes are mosaics of elements that compose the landscape itself (Fig. 1). The *spatial heterogeneity* that emerges from the mosaic influences multiple ecological processes within the landscape and arises from the processes operating within the landscape (Pickett and Cadenasso 1995). The process of moving water creates rivers and associated riparian ecosystems that are elements of watersheds and contribute to landscape heterogeneity. Watersheds, in turn, affect multiple processes within the landscape such as nutrient movement as dissolved nutrients flow towards streams in watersheds and influence, and are influenced by, nutrient cycling in riparian zones. Wetlands also contribute to landscape heterogeneity and, like riparian ecosystems (Ward et al. 2002), are heterogeneous in space and time. Larkin (2017) describes types and sources of wetland heterogeneity and how wetland heterogeneity impacts community dynamics and ecosystem functions such as carbon sequestration and denitrification.

Disturbance also contributes to landscape heterogeneity (Levin and Paine 1974), and disturbance parameters such as severity, duration, and frequency are influenced by the patterns and locations of elements within the landscape. For example, natural disturbances such as floods can scour soil and vegetation, sculpting the floodplain and creating a patchy environment (Fig. 2). Watershed size and shape, relief ratio, and depth to bedrock are some landscape elements that impact flood disturbance parameters. A steep fan-shaped watershed with a high relief ratio increases flood magnitude and shallow bedrock decreases the time it takes for a flooding stream to reach bankfull stage.

Fig. 1 Heterogeneous riparian landscape consisting of abiotic and biotic components such as stream, soil, boulders, vegetation, and other organisms (Photo by Jere Boudell)

Fig. 2 Flooding of the San Pedro River, Arizona USA (Photo by Juliet Stromberg)

One of the functional outcomes of disturbance is that it produces areas, or patches, of newly available resources. This creates an opportunity for *patch/gap dynamics* (Levin and Paine 1974; Pickett and White 1987), further contributing to landscape heterogeneity. Patch/gap dynamics occur as species take advantage of the

Fig. 3 Regeneration from the seed bank after simulated flood scour (Photo by Jere Boudell)

newly available resources released by the disturbance by dispersing or immigrating into gaps and successfully inhabiting the previously occupied space. For instance, in response to floods, buried and dispersed wetland seeds once exposed to light and water can germinate and occupy the space created when floods scour vegetation and surface soils (Fig. 3).

Scale and Scaling Issues

The issue of *scale* is integral to the discipline of landscape ecology, and ecology in general (Wiens 1989; Levin 1992). Pattern, process, and scale are interrelated concepts. Phenomena can change spatially from millimeters to kilometers and temporally from seconds to centuries. Phenomena can also change through levels of organization from cells to ecosystems. For example, the pattern and process of nutrient cycling varies over the scale of meters to kilometers, minutes to eons, and from individual organisms to the ecosphere. Hierarchy theory incorporates scale and describes a system and its components. Within a hierarchical system, the top level of the system constrains the focus level and the lower level components impact and provide the mechanism that explains what is happening at the focus level (Turner et al. 2001). An investigator incorporating hierarchy theory into his/her investigation of plant productivity in wetlands needs to be cognizant of the top or broad scale controls on plant productivity such as climate and the bottom or finer scale controls such as light, water, and nutrient availability in plant microenvironments.

Scaling issues arise when investigators seek to understand phenomena and must pick the appropriate spatial and temporal scale and organizational level at which to study the phenomena. They can be confounded by scaling issues if they seek to apply their understanding of the phenomena to other scales and levels. Knowledge and application of scaling theory and methods can help investigators cope with scaling issues (Peterson and Parker 1998; Wu 2009b).

Connectivity and Fragmentation

Connectivity links landscape elements (Taylor et al. 1993). Connectivity also describes the flows of materials, such as water and nutrients, across landscapes as well as species dispersal and migration (Fig. 4). Research on connectivity typically focuses on the patterns and dynamics that significantly impact organisms that are reliant upon functional links through the landscape. The movement of water between wetlands, between groundwater and wetlands, and of migratory birds and amphibians among wetlands requires, and effectively constitutes, functional links between wetlands. Connectivity between wetlands and the role of connectivity in migration and wetland protection is discussed by Rittenhouse and Peterman. *Landscape genetics* focuses on the movement and interaction of elements and species within the landscape and the resulting effects on gene flow (Holderegger and Wagner 2008). Spear describes this newly emerging field in an essay on landscape genetics in wetlands and how it is being applied to understand in what way landscape elements and configurations impact gene flow of wetland species.

Metapopulations (Hanski and Gilpin 1997) and *metacommunities* (Holyoak et al. 2005) describe networks of populations and communities, respectively, whose members disperse between constituent populations and communities and potentially interact. Without linkage between populations and communities within the networks, these systems become fragmented, and metapopulations and metacommunities fall apart. Schooley and Cosentino discuss metapopulation theory and its application in the conservation of wetland species. A natural extension of metapopulation theory, metacommunity theory, is described by Boudell in an essay on metacommunity dynamics in riparian and lotic ecosystems. *Source-sink dynamics* of species, a component of metapopulation and metacommunity theory, occur as individuals migrate or disperse from robust populations to sparse populations. These dispersal dynamics ultimately help prevent local extinction of smaller, less successful populations (Pulliam 1988). Peterman and Rittenhouse follow up their essay on

Fig. 4 Wetland hydrologically connected to a nearby stream (Photo by Jere Boudell)

connectivity with an essay on source-sink dynamics in wetlands. Here they focus on source-sink dynamics of amphibians and reptiles and on the variety of methods used to study these dynamics.

Fragmentation of the landscape whether created by natural perturbations such as landslides or more commonly by humans through road construction and other activities disrupt connectivity within the landscape (Fisher and Lindenmayer 2007) (Fig. 5). As a consequence, fragmentation impacts landscape elements and interrupts ecological processes such as metapopulation and source-sink dynamics that are dependent on robust connections. Indeed, it is challenging to describe the many ecological processes that require connectivity without discussing fragmentation impacts. Thus, many of the aforementioned essays include discussions of fragmentation impacts. Cosentino and Schooley explicitly describe the effects of fragmentation on wetlands and specifically, the impact of fragmentation on dispersal and its outcome on biodiversity.

The Human Element

Humans are profoundly connected to the landscape they inhabit. Like other animals, our lives are significantly influenced by the environment affecting where and how we live. As a successful dominant species and as ecosystem engineers we, in turn, affect our environment. In recognition of the reciprocal nature of our relationship with the environment, landscape ecologists have explicitly included the human element within the discipline. Landscape ecology, particularly as it is practiced in Europe, has focused on how our surrounding landscape

Fig. 5 Riparian landscape fragmentation caused by repeated mowing (Photo by Jere Boudell)

influences where live, where we grow our food, where we recreate, and how these factors impact us culturally (Farina 2007). Its principles have been included in the applied sciences of conservation, management, restoration, sustainable agriculture, and landscape design. For example, maintaining connectivity and understanding how fragmentation disrupts landscape genetics, source-sink dynamics, and metacommunities are essential in order to manage and conserve species and allows managers to predict how species will react to the fragmented landscapes they inhabit.

In many of the contributed essays in the *Landscape Ecology of Wetlands* section, authors describe how to manage to maintain connectivity and/or mitigate the outcomes of disruption to the myriad dynamics occurring within the landscape. Several contributors solely focus on conservation and attempts to ameliorate anthropogenic impact on the environment through management and restoration of wetlands and riparian areas. Zedler and Miller describe the need for, and efforts to, restore degraded wetlands at the landscape scale. Ma focuses on the role of riparian buffers, the interface between streams and impacted lands such as agricultural fields, not only in wetland protection and water quality maintenance but also as habitat for many species.

Future Directions

Landscape ecology, as a relatively new discipline, is still evolving and defining itself. Many of the early issues that arose as the field was developing have been partially resolved through attempts to unify the European and North American perspectives on landscape ecology. And yet, there is room for further integration of the basic and the applied sciences within the discipline (Wu and Hobbs 2002; Wu 2009a). There are still topics to be investigated within the field such as interactions between the varying causes of spatial patterns, further exploration of heterogeneity, and looking beyond the typical temporal scale of many studies (Turner 2005). Our changing climate and its impact on disturbance regimes and species migration and dispersal are important topics that can benefit from the holistic approach of landscape ecology.

Landscape ecology has great potential to improve conservation and management. Indeed, the call was issued for applied landscape ecology as a subdiscipline in hopes that landscape ecology principles can be tested and incorporated into conservation, management, and restoration (Turner 2005). Wetland ecology can benefit from incorporating a broader view of the landscape by including both individual wetlands and surrounding environments and how patterns and processes can interact to influence ecological phenomena at multiple spatial and temporal scales. Wetland science can only improve and become more effective at solving pressing issues such as species conservation in the face of a continually fragmented and changing environment by incorporating landscape ecology principles and methods.

Connectivity of Wetlands

11

Tracy A. G. Rittenhouse and William E. Peterman

Contents

Abstract

Connectivity implies connection or movement of resources across the landscape. Wetlands are dynamic ecosystems imbedded within or at the edges of larger systems and thus wetlands are natural "connectors" between upland and aquatic systems. Although many ecological processes have been used to describe wetland connectivity, here the focus is the movement of water and animals within and among wetlands as these are known agents of connectivity. Prior to these examples, a brief discussion of how connectivity has been used in the legal protection of wetlands demonstrates why connectivity is important to the conservation of wetlands.

Introduction

Connectivity implies connection or movement of resources across the landscape (Taylor et al. 1993). It is widely accepted that connectivity is an important ecological process that greatly influences resource patterns on the landscape. Research addressing this topic has identified several forms or definitions of connectivity. One common distinction is between structural connectivity and functional connectivity (Baguette and Van Dyck 2007). In other words, how connected is the vegetation or land cover on the landscape as opposed to how connected are populations, species, or ecosystem processes as a result of landscape features. Alternatively, connectivity has been defined based on three classifications: landscape connectivity, habitat connectivity, and ecological connectivity (Fischer and Lindenmayer 2007).

Wetland connectivity results from the connections provided by both biotic and abiotic resources, including water, nutrients, carbon, pollutants, and wildlife species, which move across the landscape. Wetlands are dynamic ecosystems at the edges of larger systems making them natural "connectors" between upland and aquatic systems (Brinson 1993). Furthermore, wetland connectivity extends to the movement of resources among wetlands that are spatially separated yet exchanges resources. Notably, the connectivity among these dynamic systems is not always readily evident, as resources may flow above, over, and below ground.

This entry focuses on the movement of water and wildlife among wetlands as these resources are widely known as common agents of connectivity among wetlands. Prior to these examples, this entry includes a brief discussion of how legal protections of wetlands have been justified based on this ecological process of connectivity.

Connectivity Used to Define Legal Protection of Wetlands

In the United States, some wetlands receive legal protection through the Clean Water Act. Regulated wetlands are defined based on their connection to navigable waters or inclusion in the definition of navigable waters (Downing et al. 2003). Therefore connectivity via the movement of water is central to the definition of regulated wetlands. The US Supreme Court case Solid Waste Agency of Northern Cook County (SWANCC) versus US Army Corps of Engineers (Corps) (351 U.S. 159, 2001) put into question federal jurisdiction over isolated wetlands. The Court found that the Corps' use of the Migratory Bird Rule, which was based on connectivity via movement of wildlife among critical wetland habitats, exceeded regulatory authority (Kusler 2001).

Legal documents use the term "isolated wetlands." This term implies that wetlands can be classified as connected or isolated. Classification is a way to simplify and improve understanding of systems, but classification does not represent the full complexity of dynamic systems. Wetland systems exist along gradients that constantly change over both space and time. Distinctions between hydrologically isolated or ecologically isolated wetlands have been made, yet the movements of water or wildlife among wetlands are both examples of functional connectivity. Guidance documents produced by the Corps are now under review and many groups have provided comments on wetland connectivity. Comments from Ducks Unlimited summarize various forms of connectivity documented in peer-reviewed literature (Schmidt 2011).

Other countries use a less regulatory approach to protection of water resources and wetlands. For example, the Water Framework Directive serves as the guiding document for maintaining and enhancing the quantitative status of all water bodies in the European Union. A review of the directive highlights the importance of connectivity and uses a definition that recognizes connectivity as process along a continuum (Peacock 2003). Connectivity is defined as “the ease with which organisms, matter or energy transverse ecotones between adjacent ecological units” (Ward et al. 1999). The review documents situations where connectivity is being lost in natural systems in the European Union, such as the loss of hydrological connections between main stem channels of rivers and other water bodies within the floodplain (Peacock 2003).

Wetland Connectivity via Flow of Water

Connectivity occurs via flow of water between wetlands and surrounding uplands, lakes, rivers, coastal waters, or other wetlands. Furthermore, it is the hydrologic conditions of wetlands that support the structure and function of these systems and provide distinctions among wetland types. The entry briefly highlights three wetland types with different hydrologic pathways. These example wetland types span the connectedness gradient and demonstrate how wetland connectivity varies across that landscape.

Ombrotrophic bogs provide a clear example of a wetland ecosystem with limited hydrologic connectivity with adjacent ecosystems. These are perched wetlands only receiving water and nutrients from precipitation and largely losing water via evaporation. Evaporation occurs as evapotranspiration through plants, and thus the level of the water table affects rate of water loss from the wetland to atmosphere (Lafleur et al. 2005).

Hydrologic connections are often hidden. For example, the prairie pothole region is a landscape that when viewed from aerial images contains a large number of spatially separated wetlands that appear to have limited connectedness via flow of water. Surface flow may differ among years with drought or abundant rainfall. The lack of surface water flow is not an indication of limited hydrologic connectivity. Pothole wetlands are fundamentally connected through groundwater (Tiner 2003). The placement in the landscape and ground water levels may influence whether a wetland is a recharge wetland, a flow through wetland, or a discharge wetland. Furthermore, the biological communities within the wetlands align along the continuum of the hydrologic connectivity to ground water (Euliss et al. 2004).

Tidal marshes and mangrove swamps provide examples of wetland ecosystems with readily apparent hydrologic connectivity. Water flows between the ocean and upland ecosystems such that the wetlands undergo daily and seasonal fluctuations of water level. Water levels that fluctuate affect salinity concentrations, transport nutrients, and aerate the soil within these wetlands (Furukawa et al. 1997; Kaplan et al. 2010; Menon et al. 2000).

Wetland Connectivity via Movement of Wildlife

Wetlands provide habitats for foraging, cover, overwintering, and reproduction to many wildlife species. Each species' unique use of wetland habitat creates connectivity with the surrounding upland habitat matrix, other wetlands, or both (Semlitsch and Bodie 2003). Disruption of movements among habitats can have profound implications for the persistence of local wildlife populations (Marsh and Trenham 2001). Migratory movements of birds among wetlands occurring at various densities and spatial patterns on the landscape affects the functional connectivity of wetlands at local, regional, and continental scales (Amezaga et al. 2002; Haig et al. 1998). A variety of other organisms also provide connectivity among wetlands including turtles, plants, and invertebrates (e.g., Roe et al. 2009).

Amphibian movements among wetlands are one apparent example of connectivity via movement of wildlife. The more common movements made by pond breeding amphibians are annual, round-trip migrations between terrestrial uplands surrounding wetlands that serve as nonbreeding habitat and wetlands that serve as breeding sites. Migratory movements have been documented by radio-tracking adult amphibians (Fig. 1) and these movements define the core habitat or life zone used by amphibians (Semlitsch and Bodie 2003). Core habitat is composed of both breeding and nonbreeding habitat (Fig. 2a). Wetland buffers must include and extend beyond core habitat to provide protection for amphibians (Semlitsch and Jensen 2001). Although the use of core habitat is highest near wetlands, local populations use habitat up to 664 m from wetlands (Rittenhouse and Semlitsch 2007; Fig. 3). Annual migratory

Fig. 1 Wood frog belted with a radio-transmitter. (Photo by Tracy Rittenhouse)

movements of amphibians connect wetlands to uplands, but can also provide connections among wetlands. For example, wood frogs breeding in vernal pools, migrate to forested wetlands for the summer, and then overwinter in upland hardwood stands (Baldwin et al. 2006). Migratory movements are distinct from the less common but ecologically very important dispersal movements (Semlitsch 2008; Fig. 2b, c).

Dispersal is the permanent movement of an individual from its birth site to the place where it reproduces (Johnson and Gaines 1990). Amphibian dispersal is a process that connects wetlands and is defined as the one-way movement from the natal wetland to a different wetland to breed (Semlitsch 2008; Fig. 2c). The majorities of individuals breed in their natal wetland and thus never disperse. Dispersal movements primarily occur during the juvenile life stage but occasionally adults may disperse. Dispersal is difficult to detect, but a 7-year mark-recapture study of marbled salamanders at 14 wetlands showed that 9% of successful breeding juveniles moved among ponds and <2% of breeding adults moved among ponds (Gamble et al. 2007; Fig. 4). Amphibian dispersal is an example of how wildlife provides connectivity among wetlands: a critical ecosystem function. Amphibian dispersal among wetlands also decreases the risk of extinction of local populations especially in short-lived species such as wood frogs, and thus successful dispersal among wetlands is crucial to the long-term persistence of amphibian populations (Harper et al. 2008).

The density of wetlands is one factor that affects connectivity among wetlands. The likelihood that amphibians will successfully disperse among wetlands is greatest when wetlands are in close proximity to one another. Connectivity among wetlands that results from amphibian movements has been used to identify areas of conservation priority for wetlands within the state of Massachusetts, USA (Compton et al. 2007). Land use in the uplands between wetlands also influences connectivity among wetlands provided by amphibians. Urban development (Hamer and McDonnell 2008; Safner et al. 2011), road or railways (Eigenbroda et al. 2008; Gibbs and Shriver 2005), and agriculture (Gagne and Fahrig 2007; Rittenhouse and Semlitsch 2006) are often highly resistant land cover types that prevent amphibian dispersal among wetlands. However, land use effects on dispersal can be nuanced upon detailed examination. For example, salamanders oriented toward and experienced lower desiccation risks in soybeans compared to corn (Cosentino et al. 2011).

Since dispersal movements involve a small proportion of an animal population, detecting connectivity among wetlands by observing the movement of individuals requires monitoring a large number of marked animals. Such endeavors are often time and cost prohibitive. Further, there is no guarantee that an observed dispersal event results in functional population connectivity via the transfer of genes. Landscape genetic methods provide an alternative approach to estimate connectivity, rate of movement, and/or differentiation of populations across the landscape (Storfer et al. 2007). Such methods are particularly suited for studies of wetlands because a wetland provides a discrete boundary from which to sample individuals. Landscape genetic approaches not only allow for the assessment of connectivity but provide a direct framework for determining the effect of the intervening habitat matrix on animal movement (Zeller et al. 2012). The effective distance between any two wetlands can be measured as a function of the intervening habitat matrix.

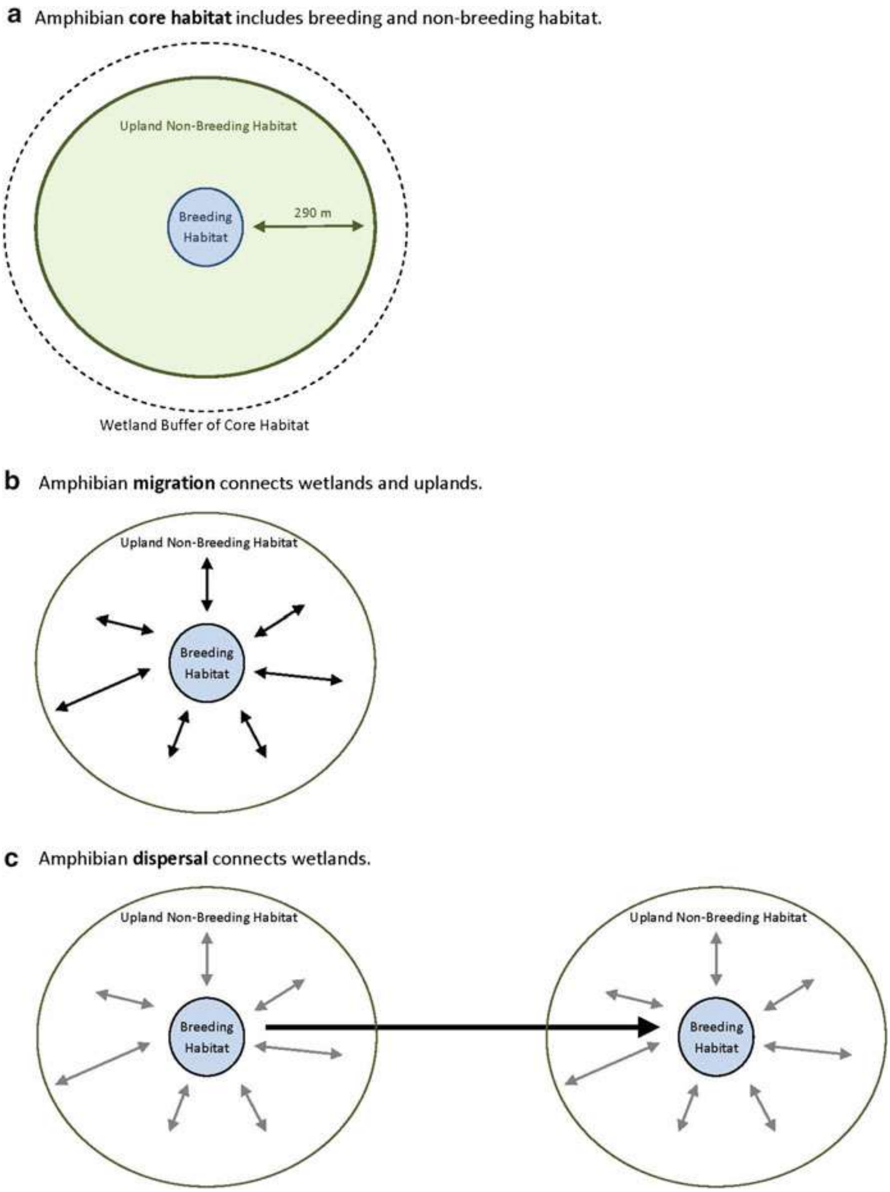

Fig. 2 Core habitat (**a**) is comprised of breeding and nonbreeding habitat. Migration (**b**) is round-trip, annual movements connecting wetlands to uplands. Dispersal (**c**) is one-way movement that provides connectivity among wetlands

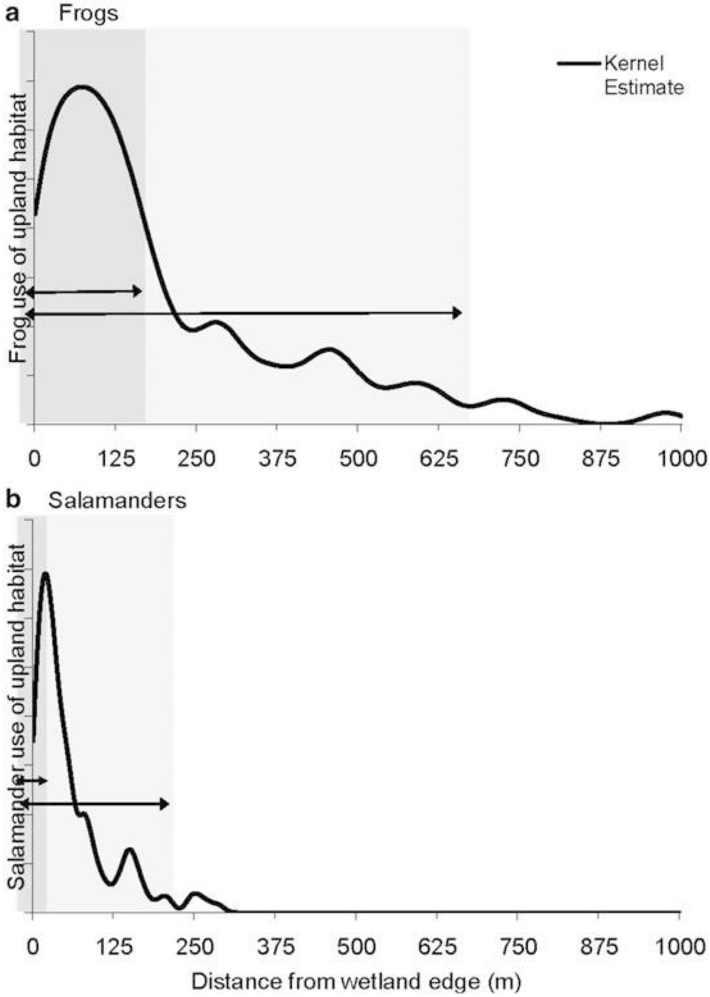

Fig. 3 Amphibian use of upland habitat surrounding wetlands. The wetland edge is at 0 m and the x-axis is the distance from the wetland edge. For frogs (**a**), 50% of a local population lives within 183 m and 95% of the population lives within 703 m. For salamanders (**b**), 50% of the local population lives within 41 m and 95% of the population lives within m. For all pond-breeding amphibians (frogs and salamanders together), 50% of the population lives within 93 m and 95% of population lives within 664 m (Reprinted from Biological Conservation, 139, Lloyd R. Gamble, Kevin McGarigal, Bradley W. Compton, Fidelity and dispersal in the pond-breeding amphibian, *Ambystoma opacum*: Implications for spatio-temporal population dynamics and conservation, 11 pp, Copyright (2007), with permission from Elsevier)

By evaluating genetic distance or gene flow estimates with these effective distance estimates, one can test a variety of hypotheses concerning the relative influence of different landscape features (e.g., roads, agriculture, etc.) as they relate to the successful dispersal of genes between wetlands.

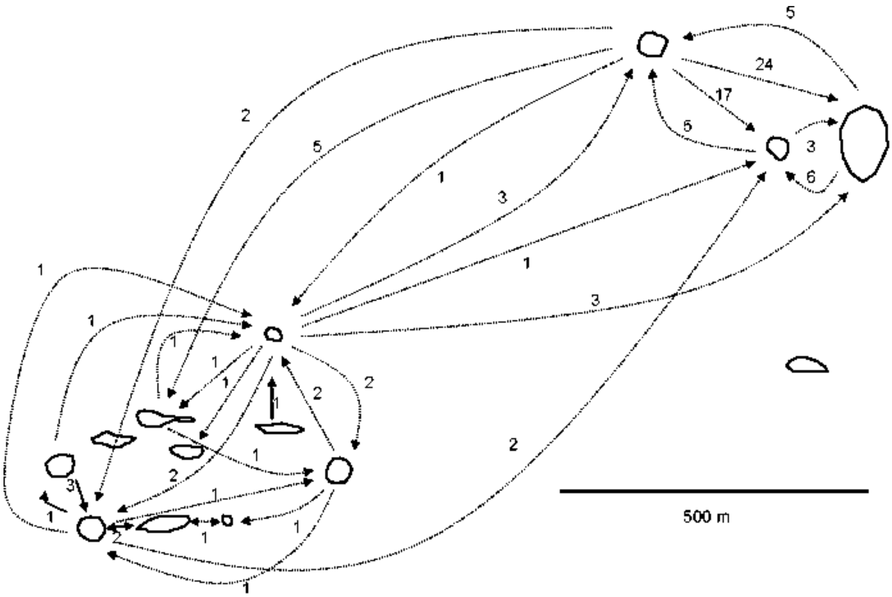

Fig. 4 This figure was published in Gamble et al. (2007) to describe a mark-recapture effort that documented the number of marbled salamanders dispersing among wetlands from 1999 to 2005 (Reprinted from Biological Conservation, 139, Gamble, McGarigal, Compton, Fidelity and dispersal in the pond-breeding amphibian, Ambystoma opacum: implications for spatio-temporal population dynamics and conservation, 247–57, 2007, with permission from Elsevier)

Conclusion and Future Challenges

Wetland connectivity concerns the movement of resources within and among wetlands. Future challenges will include how climate change is and will continue to alter connectivity in wetlands (Roelke et al. 2012). Hydrological flows among wetlands as well as the abundance of wildlife moving among wetlands are dynamic processes providing functional connectivity. These processes vary spatially and temporally, changing with climate and land use (Johnson et al. 2010; Wright 2010). Wetlands may become more or less functionally connected if the frequency between droughts and floods change, which may severely impact connectivity and metapopulation capacity of wetland networks in the future (Wright 2010). Alternatively, the magnitude of these events may change while the frequency remains relatively constant. Is wetland connectivity the same in a system with high magnitude/low frequency of movement as opposed to a system with low magnitude/high frequency? Furthermore, altered flow regimes within riverine systems are known to greatly affect biodiversity within wetlands. As climate change results in altered precipitation patterns, one should expect that effects on biodiversity in other wetland types could be as evident as that described in riverine wetlands (Bunn and Arthington 2002).

A difficult aspect of understanding connectivity via animal movement is the behavior and motivation of each individual in the population. Experiments that seek to describe these characteristics, such as movement rate, distance, path sinuosity, etc., often reveal tremendous intrapopulation variation. A promising future research path is the incorporation of these fine-scale, experimental data on movement behavior to parameterize individual-based models (IBMs) (DeAngelis and Mooij 2005). Such models incorporate individual variation in behavior, while assessing the broader-scale properties that emerge from simulation experiments. Once parameterized, IBMs can be utilized to conduct virtual experiments to determine the effects of land use, fragmentation, and habitat loss on movement and connectivity.

Although genetic data provide direct estimates of realized movement (i.e., gene flow), there is still great difficulty and uncertainty in determining the effects of the intervening habitat matrix on movement (Zeller et al. 2012). Resistance values for landscape features are often determined based upon expert opinion, but such approaches should be used with caution as expert-parameterized models may perform suboptimally (Charney 2012). Analytical methods and frameworks for determining optimal landscape resistance values as they relate to movement and/or genetic data remain an area of active research. Methods for determining least-cost paths (Sawyer et al. 2011) or landscape resistance (McRae 2006) are continually being evaluated and developed, and their integration with tools for assessing connectivity (Carroll et al. 2012) should make future regional assessments of wetland connectivity much more objective.

One caveat to promoting wetland connectivity is the potential for invasive species to propagate throughout the wetland network (Aquiloni et al. 2005; Peterson et al. 2013). Invasive species such as red crayfish (*Procambarus clarkii*) and the North American bullfrog (*Rana catesbeiana*) can have dramatic effects on local wetland processes and biodiversity. Further, wetlands are particularly susceptible to invasion by nonnative plants (Zedler and Kercher 2004). While functional connectivity of wetlands is critical for the maintenance of native biodiversity, serious consideration must be given to the potential for invasive species colonization.

Definition

Corridors are contiguous areas of land, which connect habitat patches together (Farina 2007; Gilbert-Norton et al. 2010). These features can also exist as routes within bodies of water or in the case of rivers; the river itself is the corridor (Fig. 1). Corridors occur as natural landscape elements, protected strips of land, or constructed pathways, which serve to connect patches and isolated habitats. These connections facilitate movement between patches and can be used by land

managers to alleviate the effects of fragmentation by providing a dispersal and migration passageway. However, just as corridors facilitate the movement of native species across the landscape, these also facilitate the movement and dispersal of nonnative species (Planty-Tabacchi et al. 1996). Within watersheds, rivers and associated riparian zones function as corridors (Naiman et al. 2005). Aquatic organisms travel across the landscape within the river network, while terrestrial organisms travel via the riparian zone where resources are often abundant. For example, seeds and other propagules are dispersed laterally across the floodplain as well as downstream when rivers flood, effectively dispersing species to other communities and potentially, other streams within the river network. Rivers often connect wetlands and thus serve as migration corridors between wetlands, particularly for wildlife that use different wetlands at different times within their life cycles (Naiman et al. 2005; Keddy 2010). Fish ladders are a type of artificial corridor that connects upstream and downstream river reaches when impoundment prevents fish migration.

Abstract

Wetlands provide habitat for a diverse array of aquatic and semiaquatic species, many of which provide direct economic and recreational value. Despite the ecosystem services provided by wetland fauna and flora, historical wetland loss has been dramatic. Wetland loss was >50% in the USA and 60–70% in Europe by the 1980s, with most losses resulting from agriculture and urban development. Although habitat loss can result from natural, stochastic events, anthropogenic habitat loss and subsequent fragmentation are among the most important drivers of biodiversity loss. One mechanism underlying the loss of biodiversity after habitat loss and fragmentation is the breakdown of wetland connectivity previously maintained by dispersal.

Introduction

Wetlands provide habitat for a diverse array of aquatic and semiaquatic species, many of which provide direct economic and recreational value (Woodward and Wui 2001). Despite the ecosystem services provided by wetland fauna and flora, historical wetland loss has been dramatic. Wetland loss was >50% in the USA and 60–70% in Europe by the 1980s, with most losses resulting from agriculture and urban development (Groom et al. 2006). Although habitat loss can result from natural, stochastic events, anthropogenic habitat loss and subsequent fragmentation are among the most important drivers of biodiversity loss (Millennium Ecosystem Assessment 2005). One mechanism underlying the loss of biodiversity after habitat loss and fragmentation is the breakdown of wetland connectivity previously maintained by dispersal.

Importance of Dispersal

For wetland species, dispersal is the one-way movement of an organism between its natal wetland and the wetland in which it reproduces (Clobert et al. 2012). Dispersal is a fundamental biological process that influences individual fitness, population dynamics, and community structure (Clobert et al. 2012). Dispersal can be essential for the maintenance of biodiversity because it increases species persistence by counteracting demographic stochasticity (i.e., rescue effect; Groom et al. 2006). Additionally, dispersal can lead to gene flow between populations, which can be important for introducing beneficial alleles into populations and minimizing the loss of genetic variation due to genetic drift and inbreeding (Groom et al. 2006).

For many insects and vertebrates, dispersal occurs through direct, active movement of individuals overland or along water corridors. For fully aquatic species such as fish, physical connections among wetlands can be essential for dispersal. Alternatively, plants and some invertebrates rely on passive dispersal of gametes or zygotes. Waterfowl play an important role in maintaining wetland connectivity over large scales by transporting the pollen, seeds, and eggs of other species, including fish (Amezaga et al. 2002).

One-way dispersal from natal to breeding wetlands can be contrasted with movements of individuals to and from breeding wetlands (i.e., migration; Clobert et al. 2012). Many semiaquatic organisms have complex life cycles with both terrestrial and aquatic stages. For example, many amphibians use uplands for foraging and overwintering and wetlands for breeding, whereas many turtles use uplands for nesting and wetlands for breeding and foraging (Semlitsch and Bodie 2003). Movement between terrestrial and aquatic habitats is critical for semiaquatic organisms to complete their life cycles. Compared to among-wetland dispersal, breeding migrations are generally completed by direct, active movements of individuals.

Landscape Connectivity in Wetland Networks

For wetland species, landscape connectivity can be defined as the degree to which the landscape facilitates movement of organisms among wetlands or between wetland and upland habitats (Taylor et al. 2006). From a physical perspective, structural connectivity depends strictly on the spatial configuration of habitat in the landscape (Taylor et al. 2006). Wetland species should have high rates of dispersal between wetlands separated by short distances, whereas dispersal should be uncommon to wetlands that are spatially isolated. Similarly, breeding migrations of semiaquatic species are facilitated when required terrestrial habitat is adjacent to a wetland. The simplest index of structural connectivity is nearest-neighbor distance, which may be calculated as the distance from a wetland to the nearest wetland or upland habitat (Calabrese and Fagan 2004). More complex measures of connectivity include graph-theoretic and incidence function metrics that incorporate spatially explicit occupancy data and information on the focal species' dispersal ability (Calabrese and Fagan 2004).

Structural connectivity can be distinguished from functional connectivity, which considers how landscape features affect the movement behavior of organisms during dispersal (Taylor et al. 2006). Landscape features vary in their effects on movement due to differential resource availability, habitat complexity, predation risk, and physiological costs. For example, movement of the tiger salamander (*Ambystoma tigrinum*), a pond-breeding amphibian, was constrained by desiccation risk in upland habitats, and desiccation risk varied dramatically among habitats (Fig. 1; Cosentino et al. 2011a). Furthermore, the effects of desiccation risk on individual movement scaled up to affect the probability that tiger salamanders colonized uninhabited wetlands across a metapopulation (Cosentino et al. 2011b; ► Chap. 20, "Metapopulation Dynamics of Wetland Species" by Schooley and Cosentino). Wetlands surrounded by habitats with low desiccation risk were more likely to be

Fig. 1 Interpond movements of amphibians are influenced by desiccation risk experienced in upland habitats. For example, desiccation risk for tiger salamanders (*Ambystoma tigrinum*) in Illinois, USA is greater in prairie and corn than in forest and soybean habitats, and individuals orient their movements towards low-risk habitats (Cosentino et al. 2011a)

colonized than wetlands surrounded by habitats with high desiccation risk. Thus, movements among wetlands or between wetland and upland habitats can be limited by the composition and spatial configuration of habitats with variable dispersal costs. Least-cost modeling can be used to quantify the distances along paths between habitats that minimize dispersal costs (i.e., effective distances, Adriaensen et al. 2003), although parameterization of least-cost models requires detailed information about how habitats in the landscape affect movement behavior.

Compared to species that move over land, connectivity for species confined to aquatic habitat (e.g., fish) depends more strongly on aquatic connections such as stream linkages and overland sheet flow. Structural connectivity for fully aquatic species is predominantly determined by distances between wetlands along stream corridors or across areas inundated by water. However, stream flow and sheet flow can both depend on precipitation, introducing temporal variation in connectivity among wetlands (Leibowitz and Vining 2003). Functional connectivity for fully aquatic species may be limited by factors such as topography (e.g., stream cascades) and predation risk experienced within streams during movement between wetlands.

Wetland Fragmentation

Habitat fragmentation occurs when habitat is reduced in size and the distance between remaining habitat patches increases. Although wetlands are naturally patchy and separated by a terrestrial matrix, structural and functional connectivity can be disrupted by habitat loss and fragmentation in two main ways. First, when wetland habitat is lost or entire wetlands are destroyed, the density of wetlands decreases and the physical isolation of remaining wetlands increases (Fig. 2, Gibbs 2000). For species that move among wetlands over land or via passive dispersal,

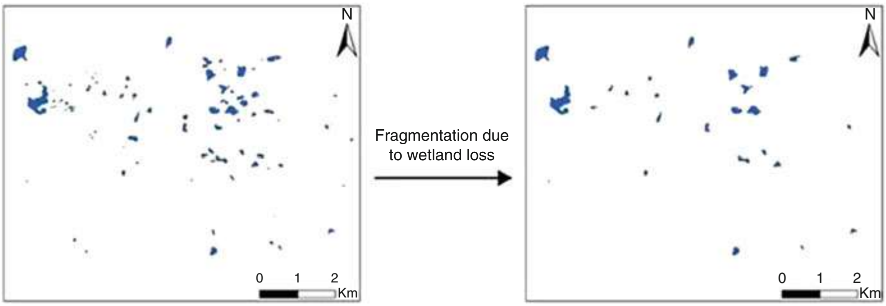

Fig. 2 Fragmentation increases spatial isolation of wetlands remaining after wetland loss

even small or isolated wetlands can be important by functioning as stepping-stones for dispersal to other wetlands (Semlitsch 2000). Thus, reducing the density of wetlands in the landscape, even small wetlands, decreases the likelihood of direct or indirect dispersal between wetlands. This reduction in structural connectivity can leave populations susceptible to extinction due to inbreeding and low population size (Clobert et al. 2012). Increased isolation also reduces the probability of colonization of uninhabited wetlands, which can be particularly important for regional persistence of species that exhibit metapopulation dynamics (Hanski and Gilpin 1997; ► Chap. 20, "Metapopulation Dynamics of Wetland Species" by Schooley and Cosentino). For species confined to aquatic habitats, the loss of stream linkages may also decrease wetland connectivity. Headwater streams are frequently lost from developed landscapes due to drainage, channelization, filling, piping, and groundwater withdrawal (Meyer and Wallace 2001).

Second, fragmentation occurs at a smaller spatial scale when terrestrial habitat surrounding wetlands is lost. Wetlands are linked to upland habitats through migratory movements of semiaquatic species (Semlitsch and Bodie 2003), and migration of semiaquatic species can be an important mechanism of energy and nutrient transfer between wetland and upland systems (e.g., Regester et al. 2008). In fragmented landscapes, maintaining wetland-upland linkages and connectivity among wetlands are primary goals for conserving biodiversity. Small, terrestrial buffer zones are often designated around wetlands to protect water resources and ecosystem services, but larger buffer zones are recommended to protect core terrestrial habitat used by semiaquatic species (Fig. 3; Semlitsch and Bodie 2003; Rittenhouse and Semlitsch 2007).

Maintaining Connectivity in Wetland Networks

In general, structural connectivity can be maintained by (1) minimizing the loss of wetlands and other aquatic habitats that function as corridors between wetlands (e.g., streams), and (2) maintaining core terrestrial habitats immediately surrounding wetlands. However, because some species move extensively among wetlands, maintenance of wetland connectivity likely requires management at the landscape scale (Amezaga et al. 2002). Within seasons, many species make temporary movements among wetlands that can vary dramatically in quality (e.g., vegetation structure, food, hydroperiod). For example, turtles tend to use permanent lakes during drought, but they move to ephemeral wetlands during periods of high precipitation (Roe and Georges 2007). Because wetlands vary in the resources they provide, conservation of wetland biodiversity likely requires a heterogeneous assemblage of wetlands each with terrestrial buffers, as well as the presence of upland habitats that allow seasonal movements and dispersal (see Fig. 3, Roe and Georges 2007).

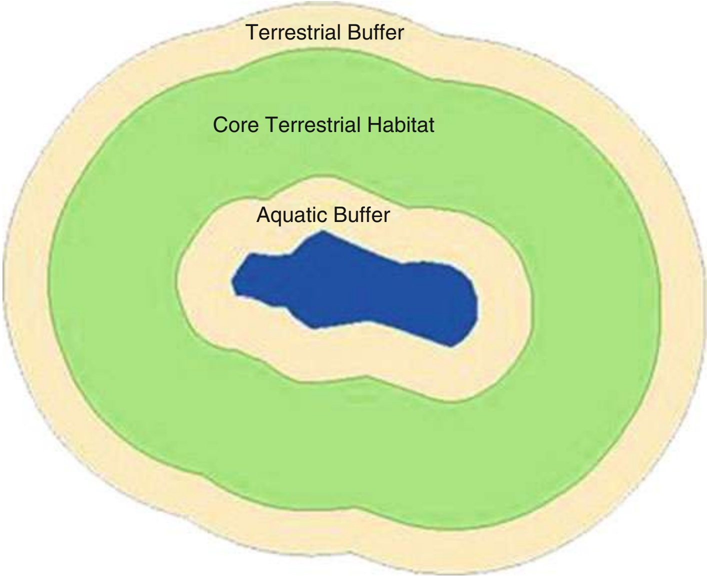

Fig. 3 Habitat buffers around wetlands are recommended to maintain wetland-upland connectivity for semiaquatic species. Semlitsch and Bodie (2003) recommend an aquatic buffer (30–60 m wide) to protect water resources, a zone to preserve core habitat for amphibians and reptiles (142–289 m, encompassing the aquatic buffer), and an additional 50-m buffer to protect core terrestrial habitat. Rittenhouse and Semlitsch (2007) indicate that some species require much greater areas of core habitat (upwards of 700 m) (The illustration is based on the original concept from Semlitsch and Bodie (2003))

Disturbance

14

Jere A. Boudell

Contents

Abstract

Disturbance is a natural process that disrupts the environment and can impact species through injury, death, or migration. A disturbance also creates landscape heterogeneity if landscape elements (e.g., logs and soil) are modified or removed. Disturbance can remove competitors and release resources, allowing new species and individuals to occupy the newly available space. These dynamics are referred to as patch/gap dynamics.

1987). Both small- and large-scale disturbances can occur. Small-scale disturbances take place when, for example, an animal digs through soil or a tree falls in a forest. Large-scale disturbances can be caused by volcanic eruptions or high magnitude floods. The degree of impact of a disturbance is related to the timing, frequency, magnitude, and duration of the disturbance. These properties are used to describe a disturbance event. For example, a 100-year flood caused by a significant weather event and significant snow melt might cause a high and sudden rise of water (Mitsch and Gosselink 2000; Naiman et al. 2005; Keddy 2010). Such an event can be described as a low frequency (approximately a 1% chance of occurring each year), high magnitude flood (high volume of water) event. This type of flood could occur during the fall (timing) and last for 1 week (duration). A flood with the aforementioned properties would impact the environment and associated species significantly.

Because disturbance can impact species considerably, it can act as a selective pressure on species inhabiting environments so that with repeated disturbances, species occupying the habitat will be adapted to such disturbances. For example, hydrology is the primary driver of disturbance that occurs at the landscape scale in wetlands and riparian (riverine) ecosystems (Mitsch and Gosselink 2000; Naiman et al. 2005; Keddy 2010). In frequently flooded riparian ecosystems, plant communities are dominated by annuals and short-lived perennials. Flooding rivers can scour vegetation and soil, deposit sediment along with propagules, and cause a temporary increase in water availability (Fig. 1). Flooding, within this context, is a natural disturbance event. Cessation of the disturbance caused by impoundment of the river by a dam would constitute an anthropogenic disturbance and significantly impact the environment and associated species that are adapted to flood disturbance.

and flood attenuation, are a few examples of ecosystem functions. Ecosystem functions vary throughout the landscape and through time. Nutrient cycling, for example, depends on multiple factors such as soil quality, microbial richness, temperature, and moisture availability, and these factors may be present in hotspots within the landscape but can also fluctuate with seasonal changes. A healthy ecosystem with all of its processes operating effectively can be described as a functioning ecosystem. When ecosystems are significantly impacted by natural or anthropogenic disturbances, ecosystem function can decline. Attempts to protect ecosystems include the identification of ecosystem functions that benefit humans. These functions are referred to as ecosystem services (Daily et al. 1997; Millennium Ecosystem Assessment 2005).

Many ecosystem functions occur within wetlands and riparian (riverine) ecosystems (Figs. 1 and 2) (Millennium Ecosystem Assessment 2005; Naiman et al. 2005;

Keddy 2010). Habitat is provided to the many species that populate these ecosystems year round or seasonally. Nutrient cycling and transport supports decomposition and the movement of nutrients up the food chain as vegetation absorb available nutrients and herbivores predate upon plants. Excess water drains from surrounding uplands into riparian ecosystems and is transported downstream. All of these functions and many more are present in healthy wetlands and riparian ecosystems.

Introduction

Ecosystem services are the many processes conducted by ecosystems, which provide resources of benefit to humans and other organisms (Cairns 1995; Daily et al. 1997; Millennium Ecosystem Assessment 2005a). Decomposition of wastes by scavengers, detritivores, and microbes; the pollination of crops and other vegetation by pollinators; and protection from UV radiation by the Earth's ozone layer are a few examples of ecosystem services that support life. Typically the inherent value of

these services only becomes apparent after the services are interrupted and the disruption impacts the quality of human life (Avise 1994; Millennium Ecosystem Assessment 2005a). Attempts have been made to monetize these services in order to underline the value of environmental conservation and the protection of our natural resources to the general public and politicians. For example, one outcome of the Biosphere 2 project was the discovery that the total cost to artificially support one person per year through the ecosystem services provided by the man-made human terrarium was $9,000,000 (Avise 1994).

Wetland Ecosystem Services

Wetlands and riparian (riverine) ecosystems provide many ecosystem services (Fig. 1) (Millennium Ecosystem Assessment 2005b). The purification of water as polluted water migrates through surrounding wetland and riparian ecosystems is a critical service, which provides clean, fresh water. Riparian ecosystems attenuate flood waters as water drains from surrounding uplands into river channels. Rivers disperse seeds and support aquatic diversity. Wetlands and riparian ecosystems provide critical habitat, which supports innumerable species. These are just a few examples of the many ecosystem services provided by wetlands and riparian ecosystems.

Fig. 1 Regeneration from the seed bank after simulated flood scour (Photo by Jere Boudell)

that were previously used by the tree are now available to other organisms. Seeds buried in the newly exposed soil may germinate into the space previously occupied by the tree and seeds from surrounding plants may disperse into the open space. The gap created by the fallen tree may also be considered a "patch." In riparian (riverine) ecosystems, patch dynamics at the landscape scale may happen relatively quickly as large floods restructure the floodplain removing whole communities and altering the environment (Naiman et al. 2005; Keddy 2010). Recovery would occur through seed dispersal from surrounding communities, germination from the seed bank, and as surviving woody species produce new shoots (Fig. 1). The patchy environment created by small- and large-scale disturbances can be viewed as a matrix of patches. The matrix of patches, the relationship between the patches, and the movement of organisms and materials such as nutrients and water between the patches are described as patch dynamics (Pickett and White 1987).

Gap and patch dynamics occur in space over the landscape and time as gaps and patches are created and filled. Patch dynamics can also be hierarchical where an ecosystem consists of a nested hierarchy of patches (Wu 1995). For example, a forest ecosystem consists of a matrix of larger patches created by a variety of events such as flooding and windfall, and within each of these patches is a matrix of smaller patches. A smaller patch created by a prior flood which has since been colonized consists of smaller patches created by fallen trees and areas disturbed by burrowing animals. Hierarchical patch dynamics would include the relationships and interactions between the levels within the hierarchy.

Definition

A patch is an area that is distinguishable within an otherwise fairly homogeneous distribution of one or more landscape elements (Pickett and White 1987; Keddy 2010). For example, a habitat patch might be identified as a community within a matrix of communities or as a localized concentration of soil nitrate (Figs. 1 and 2). A patch might also refer to an area of resources that becomes available after a tree has fallen or as an ecosystem remnant created via landscape fragmentation. Patchy ecosystems' become elements of the overall landscape matrix and contribute to landscape heterogeneity. Patches are often created through disturbance, and the processes that arise to create the patches and functional interplay within and between the patches are referred to as patch dynamics.

In wetlands and riparian (riverine) ecosystems, patches are created through a variety of processes (Keddy 2010). Patches may arise through disturbance caused by beaver or muskrats, for example, or by flooding as flood waters aggrade and degrade floodplains (Keddy 2010). Fire can create patches in Everglades wetlands via peat

burnings (Keddy 2010). Communities within riparian ecosystems, such as *Populus-Salix* (cottonwood-willow) forests in southwestern riparian ecosystems in the USA, can be destroyed during flood scour but reestablish in another location after seed dispersal from surrounding surviving populations.

Metacommunity Dynamics of Riparian Ecosystems

19

Jere A. Boudell

Contents

Abstract

A metacommunity is defined as a network of communities populated by potentially interacting species that are linked across landscapes through dispersal. Metacommunity theory unifies landscape or regional processes, namely dispersal, with local processes such as niche dynamics. This unification of ecological theories can provide wetland and riparian ecologists with a framework to understand how community structure and dynamics are impacted by both regional and local processes. Understanding how processes occurring at different scales structure wetland communities can help wetland ecologists predict how landscape fragmentation impacts biodiversity and ecosystem functioning.

Introduction

A metacommunity is defined as a network of communities populated by potentially interacting species that are linked across landscapes through dispersal (Hanski and Gilpin 1991; Wilson 1992; Holyoak et al. 2005). Metacommunity theory unifies landscape or regional processes, namely dispersal, with local processes such as niche dynamics. This unification of ecological theories can provide wetland and riparian ecologists with a framework to understand how community structure and dynamics are impacted by both regional and local processes. Understanding how processes occurring at different scales structure wetland communities can help wetland ecologists predict how landscape fragmentation impacts biodiversity and ecosystem functioning (Holyoak et al. 2005).

Historical Background

Early metacommunity work focused on developing mathematical models (Wilson 1992; Mouquet and Loreau 2003) and testing model predictions (Cottenie 2005; Morgan Ernest et al. 2008). Four paradigms or models arose from this early work, and the majority of metacommunity research concentrated on evaluating the models experimentally and descriptively (Logue et al. 2011).

The four models that describe metacommunity dynamics all assume that species within metacommunities are able to disperse to all constituent communities (Leibold et al. 2004; Chase et al. 2005). What varies between the models is the degree of similarity between the communities, and the degree of impact of regional (e.g., dispersal) and local (e.g., environmental, interspecific interactions) processes on community characteristics such as taxonomic abundance, composition, and diversity (Holyoak et al. 2005).

The neutral and patch dynamics models propose that communities are similar and not explicitly distinct. In the neutral model, species within communities are functionally equivalent and species extinction occurs randomly due to demographic variation, resulting in "ecological drift" (Hubbell 2001, 2005). The patch dynamics model makes a similar prediction about species equivalency for most traits, but species vary in their competition-colonization abilities and species diversity is limited by dispersal (Leibold et al. 2004).

The two remaining metacommunity models state that communities are not similar and predict that species sort along environmental gradients (Holyoak et al. 2005). According to the species-sorting model, communities are arrayed along some environmental gradient and species populate the communities according to how their life-history trade-offs allow them to be successful (Chase et al. 2005). Dispersal does not allow a species to overcome its niche limitations. In the mass effects model, species are also limited by niche boundaries; however, dispersal enables a species to surmount niche restrictions (Holyoak et al. 2005). For example, a sink population may be sustained in a community in which a species is not typically successful because individuals are dispersed from source populations located in other communities (source-sink dynamics) (Mouquet and Loreau 2003).

Further work on metacommunity theory focused on incorporating additional local processes and evolutionary dynamics, understanding why evidence exists for multiple models, and investigating metacommunity dynamics in novel environments. Competition (Amarasekare et al. 2004) and predator-prey interactions (Pillai et al. 2011) are a few examples of local factors other than environment that have been investigated and included in the metacommunity framework. Urban and Skelly (2006) advocated for the inclusion of evolutionary approaches in metacommunity research as adaption impacts and interacts with a variety of local and regional processes. Other investigators have attempted to reconcile the four metacommunity models because they are not mutually exclusive in their predictions, and evidence supports multiple models, principally species-sorting and mass effects. Approaches have ranged from parsing communities into species guilds and matching results to the four models (Boudell and Stromberg 2008; Driscoll and Lindenmayer 2009) to suggestions that scale issues and temporal dynamics in metacommunities result in studies producing evidence that match multiple model predictions (Driscoll and Lindenmayer 2009). Finally, investigations of metacommunity dynamics in novel ecosystems reveal how metacommunity dynamics vary with different groups of organisms and across ecosystems. Riparian and lotic ecosystems are two prime examples.

Metacommunity Dynamics of Riverine Ecosystems: Riparian and Lotic

Riparian landscapes are excellent examples of metacommunities because they are spatially structured with constituent communities arrayed along moisture gradients that are connected by large-scale flood pulse dispersal (Fig. 1) (Naiman et al. 1993; Middleton 2002). Many plant species with varying life-history traits populate communities located along a declining moisture and flood disturbance gradient (Fig. 2) (Naiman et al. 2005). Investigations of southwestern riparian metacommunities found dispersed propagules (seeds and vegetative remnants capable of resprouting) across entire floodplains, linking the various floodplain communities together through a regional propagule bank (Figs. 2 and 3) (Boudell and Stromberg 2008). The regional propagule bank enables floodplain species to respond to changing environmental conditions locally by providing a pool of propagules that can successfully germinate or resprout in communities when supportive environmental conditions exist. Both the species sorting and mass effects metacommunity models make reasonable predictions about southwestern riparian metacommunities (Boudell and Stromberg 2008). Wetland plant species exhibit strong species-sorting dynamics as they are adapted to specific moisture conditions and are unable to overcome niche limitations through dispersal. Whereas facultative wetland species may be able to persist in communities outside their ideal moisture range due to source-sink dynamics and so match mass-effects model predictions (Boudell and Stromberg 2008). While environment was found to have a strong impact on southwestern riparian plant

Fig. 1 Researcher seining for seeds in the Verde River, Arizona (Photo taken by Danika Setaro)

communities, Muneepeerakul et al. (2008), using a neutral theory approach, demonstrated the importance of dispersal directionality and landscape structure to riparian plant diversity.

The application of metacommunity theory to lotic, or instream riverine ecosystems, is relatively new and has revealed unique challenges (Swan and Brown 2011). Riverine ecosystems form dendritic networks and this hierarchical network can constrain dispersal (Fagan 2002; Auerbach and Poff 2011; Brown et al. 2011). Because aquatic species such as fish and invertebrates are typically mobile, and water movement and dispersal of aquatic organisms are oriented downstream, the formation of distinct communities can be confounded (Auerbach and Poff 2011; Brown et al. 2011). Despite these challenges, metacommunity research in lotic ecosystems has found support for species-sorting and mass-effect dynamics (Brown and Swan 2010; Auerbach and Poff 2011). A graphical model of riverine metacommunity dynamics by Brown et al. (2011) illustrates the unique dispersal dynamics of lotic organisms and the potential impact of local factors on community structure and species interactions (Fig. 4). Metacommunity theory promises to be a

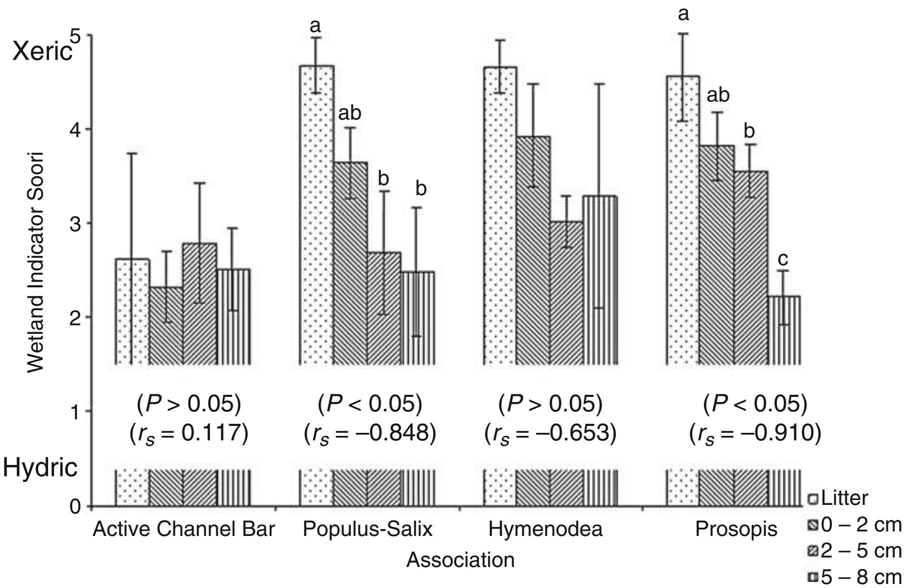

Fig. 3 Mean wetland indicator score, ±1 SD, per m^2 by community (association) and depth in a southwestern riparian plant metacommunity. Wetland (hydric) species have lower wetland indicator scores. Communities are arranged along a distance gradient with active channel bar closest to the river channel. Results are from ANOVA and correlation analyses (Depth vs. wetland indicator score; modified from Boudell and Stromberg 2008)

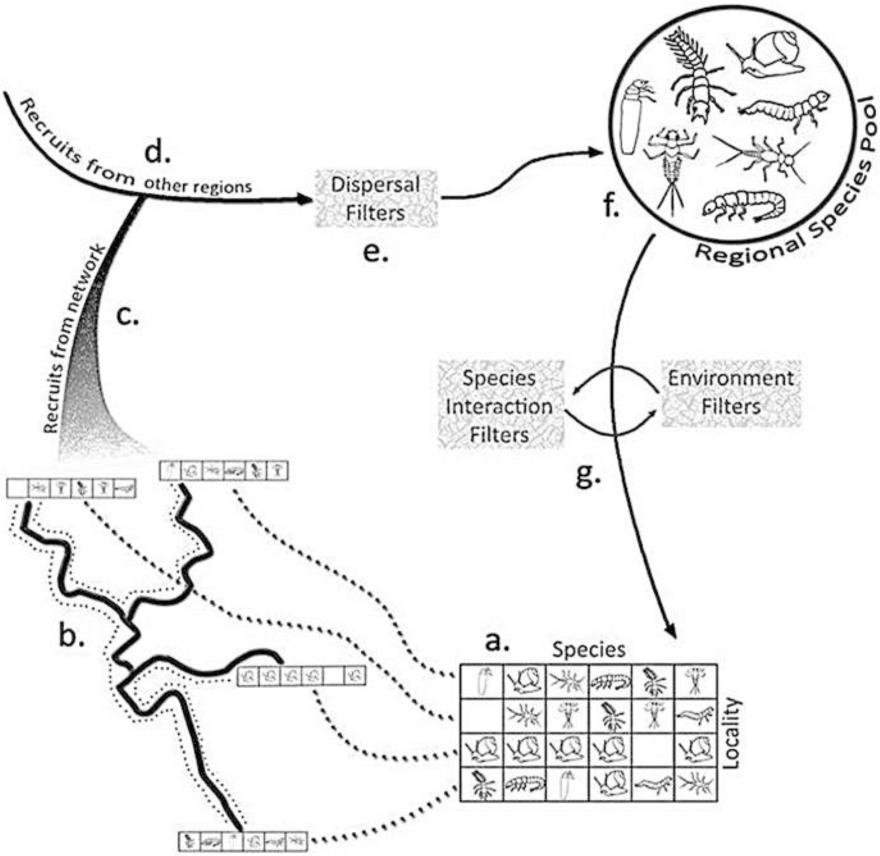

Fig. 4 Interactions between local (environmental conditions and species interactions) and regional factors (dispersal and landscape-scale extinction dynamics) in determining local community composition in riverine metacommunities. (**a**) The regional species pool represents the organisms available to occupy particular localities. (**b**) Organisms from the regional species pool are filtered based on environmental factors and species interactions. (**c**) A local community can be defined as an assemblage of species within a particular habitat. In this case, each table cell is a microhabitat within a local community occupied by a particular species or left unoccupied (*blank cells*). (**d**) The riverine network. *Large dotted lines* illustrate the location of each local community in the habitat x species matrix. *Small dotted lines* represent dispersal between local communities in the riverine network. (**e**) Dispersal of recruits into the regional species pool. This pathway includes both within-network dispersal (also illustrated by the *small dotted lines* in [**d**]) and out-of-network dispersal. (**f**) Recruits from other regions (i.e., neighboring riverine networks) that can potentially contribute to the regional species pool. (**g**) Dispersal filters, which are limits or barriers to the dispersal of organisms from a locality into the regional species pool. Filters may be particular to a species, or may affect any number of species. (Benthic macroinvertebrate illustrations are courtesy of Laura E. Smith. Reprinted with permission from Brown et al. (2011))

powerful tool to understanding community assembly of lotic organisms (Brown et al. 2011; Swan and Brown 2011).

Future Directions

As theoretical and empirical work on metacommunity dynamics continues, new questions and developments arise. The integration of the four metacommunity models and incorporation of other processes such as predator-prey interactions and evolutionary processes will produce a more comprehensive theory that realistically incorporates the multiple factors that structure communities (Boudell and Stromberg 2008; Driscoll and Lindenmayer 2009; Logue et al. 2011). Exploring metacommunities in varying ecosystems, such as wetlands and riparian ecosystems, and focusing on the community dynamics of a variety of species should also contribute to the development of a more powerful theory capable of predicting community structure and dynamics (Logue et al. 2011).

Perhaps the ultimate challenge for metacommunity theory is the ability to accurately predict the outcome of landscape fragmentation. The metacommunity framework provides a key approach to asking questions related to the management and restoration of riparian and lotic ecosystems. Individual species and communities will respond to anthropogenic disturbances such as dams, diversions, and levees, which dramatically alter environmental conditions and can disconnect constituent communities from riparian metacommunities. As wetland and riparian ecosystems are continually degraded and lost, it is more important than ever to understand how landscape fragmentation results in disruption of dispersal dynamics and how this disruption impacts local communities.

Metapopulation Dynamics of Wetland Species

20

Robert L. Schooley and Bradley J. Cosentino

Contents

Abstract

For species inhabiting naturally patchy or fragmented landscapes, conservation often is guided by metapopulation theory. A metapopulation is a set of spatially separated populations connected by movement of individuals among populations. The metapopulation can persist, despite extinctions of local populations, if populations are connected enough to allow for adequate recolonization of vacant habitat. Because wetlands occur as geographically isolated habitats, many wetland-associated species could display metapopulation dynamics. However, classical metapopulations may be rare, and metapopulations can have a diversity of spatial structures. Practical metapopulation approaches are grounded in the "area-isolation paradigm" in which the area of a habitat patch is the main predictor of local extinctions, and connectivity to other source populations is the main predictor of colonization. The generality of the area-isolation paradigm has been questioned, however, and its shortcomings relate to the need to consider habitat heterogeneity. Wetlands can differ in habitat quality and they are embedded in a heterogeneous terrestrial matrix. Functional connectivity of metapopulations depends on how movements of individuals interact with the terrestrial habitat

Introduction

For species inhabiting naturally patchy or fragmented landscapes, conservation often is guided by metapopulation theory (Hanski and Gaggiotti 2004). A metapopulation is a set of spatially separated populations connected by movement of individuals among populations. The whole metapopulation can persist, despite extinctions of local populations, if populations are connected enough to allow for adequate recolonization of suitable but vacant habitat. This on-and-off blinking of populations reflecting a balance between local extinctions and recolonizations is the hallmark of classical metapopulation dynamics (Fig. 1). The metapopulation concept was formalized by Levins (1969), but it has deeper roots including ideas on spatial dynamics of populations promoted by Andrewartha and Birch (1954). Maturation of the metapopulation approach and its application to biodiversity conservation, however, has mainly resulted from development of practical metapopulation models by Hanski and his colleagues (Hanski 1997; Hanski and Gaggiotti 2004).

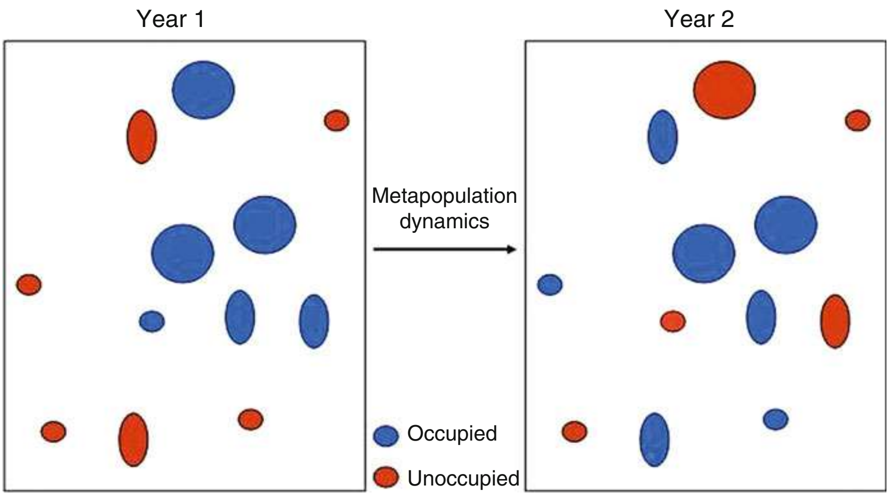

Fig. 1 Metapopulation dynamics for a hypothetical network of 12 wetlands. Wetlands in blue are occupied by a species; wetlands in red are unoccupied. Some wetlands experience local extinctions between years, and some vacant wetlands are recolonized

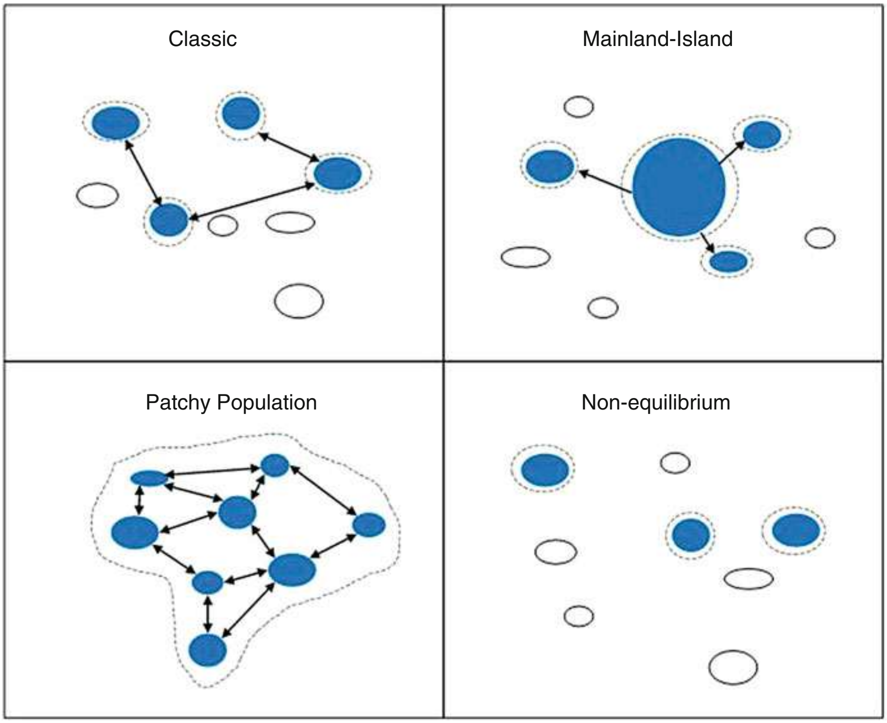

Fig. 2 Types of metapopulations (Harrison and Taylor (1997) with permission of Elsevier). Filled circles represent occupied wetlands; open circles represent unoccupied wetlands. *Arrows* indicate dispersal; *dotted lines* indicate boundaries of local populations. Metapopulation structure depends on degree and directionality of dispersal among wetlands

Hanski (1997) provided four conditions for a classical metapopulation: (1) suitable habitat occurs as discrete patches that can be occupied by local breeding populations, (2) the largest local population still has a nontrivial risk of extinction, (3) habitat patches are not too isolated so that recolonization is possible, and (4) local populations have asynchronous dynamics. Because wetlands often occur as geographically isolated habitats, many wetland-associated species could display metapopulation dynamics (e.g., Sjögren Gulve 1994; Schooley and Branch 2009). However, Marsh and Trenham (2001) warned against a naïve adoption of the "ponds-as-patches" view for wetland species such as amphibians that might not always function as metapopulations. More generally, Harrison and Taylor (1997) cautioned that classical metapopulations could be rare and that metapopulations in nature can have a diversity of structures including mainland-island, patchy population, nonequilibrium metapopulation (Fig. 2), and mixed structures at different spatial scales.

Area-Isolation Paradigm

Practical metapopulation approaches (Hanski and Gaggiotti 2004) are grounded in the “area-isolation paradigm” in which the area of a habitat patch is the main predictor of local extinctions, and connectivity to other source populations is the main predictor of colonization. For wetland species, large wetlands should contain relatively large populations and thus be less susceptible to extinction due to demographic stochasticity than are small populations occupying small wetlands. This area effect on local extinction probability holds true for some spatially structured wetland species such as round-tailed muskrats (*Neofiber alleni*; Schooley and Branch 2009) and painted turtles (*Chrysemys picta*; Cosentino et al. 2010). Size of wetlands also can affect colonization probabilities through the target effect in which larger wetlands are more likely to be colonized by individuals dispersing from other wetlands (Schooley and Branch 2009; Cosentino et al. 2010, 2011). Colonization of vacant wetlands should depend most on how isolated they are from other occupied wetlands. In fact, colonization probability has been positively correlated with connectivity for wetland-associated wildlife (Schooley and Branch 2009; Cosentino et al. 2010, 2011). Connectivity of wetlands can also reduce the likelihood of local extinctions through the rescue effect in which populations are bolstered by dispersers and maintained above levels highly vulnerable to effects of demographic stochasticity (Brown and Kodric-Brown 1977; Cosentino et al. 2011). For instance, isolated populations of the pool frog (*Rana lessonae*) in Sweden are more extinction prone than are more connected populations (Sjögren Gulve 1994).

Despite this evidence that patch area and isolation can be important predictors of extinction-colonization dynamics, the generality of the area-isolation paradigm has been questioned. Pellet et al. (2007) tested the ability of area and isolation to predict metapopulation dynamics of 10 species from diverse taxa including amphibians and concluded there was not overall strong support for these two key variables arising from metapopulation theory. Patch size may not always be a good surrogate for population size, and patch isolation measured as simple, straight-line distances among patches may be inadequate (Pellet et al. 2007). Likewise, Prugh et al. (2008) conducted a meta-analysis of 785 animal species and concluded that patch area and isolation explained a surprisingly small amount of the variation in patch occupancy (i.e., the outcome of extinction and colonization processes).

Habitat Heterogeneity and Metapopulations

Many of the shortcomings of the area-isolation paradigm as applied to metapopulations relate to the need to consider habitat heterogeneity in multiple ways. Real landscapes are not binary; wetlands can differ in habitat quality and are embedded in a heterogeneous terrestrial matrix (Schooley and Branch 2007, Prugh et al. 2008). Habitat quality of wetlands can depend on many factors including hydroperiod, water chemistry, vegetation composition, resource abundance, and predation risk (e.g., Sjögren Gulve 1994; Cosentino et al. 2010, 2011). For instance,

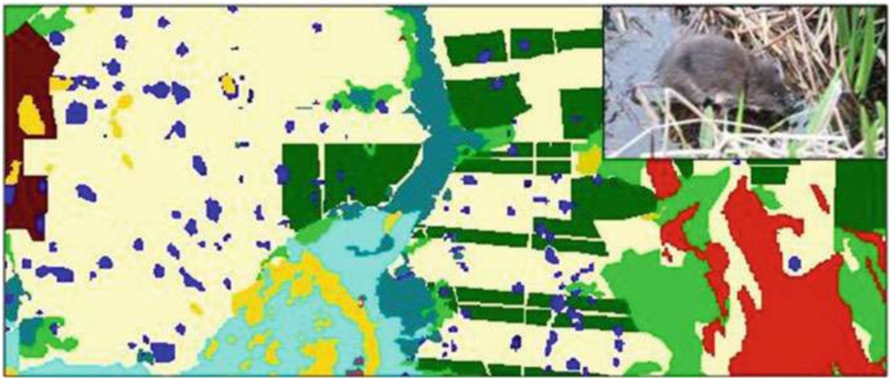

Fig. 3 The round-tailed muskrat (*Neofiber alleni*) is a species of conservation concern that exhibits metapopulation dynamics across depression marshes (*blue polygons*) in Florida, USA. Local extinctions and recolonizations depend not only on wetland area and geographic isolation, but also on habitat quality of wetlands and upland habitat between wetlands (Schooley and Branch 2009). Occupancy is less likely for wetlands surrounded by pine plantations (*dark green polygons*) and other forested upland habitat

site occupancy by round-tailed muskrats strongly depends on the cover of maidencane grass (*Panicum hemitomon*) in marshes because maidencane is the main diet item for muskrats, and they use it to build lodges (Fig. 3; Schooley and Branch 2007, 2009). Ignoring habitat quality is the likely reason that wetland size might not be a good substitute for local population size. In some situations, habitat quality can be the main driver of species distributions, extinctions are not stochastic but instead deterministic due to habitat becoming unsuitable, and species form a habitat-tracking metapopulation across fragmented landscapes (Thomas 1994). Habitat quality of wetlands could also affect colonization if dispersers actively select habitat before settling (Clobert et al. 2012), or the quality of nearby wetlands acting as sources of dispersers is variable in space (Schooley and Branch 2011).

Dispersal is a complex process influenced by many factors (Clobert et al. 2012). Functional connectivity of metapopulations depends on structural aspects of the landscape such as geographic isolation of wetlands, but also how movements of individuals interact with the terrestrial habitat matrix (▶ Chap. 13, "Dispersal and Wetland Fragmentation" by Cosentino and Schooley). Wetland pairs separated by the same straight-line distance could have different functional connectivity because the intervening habitat matrix varies in terms of movement costs (Fig. 3). For example, movement of Natterjack toadlets (*Bufo calamita*) is affected by land cover with forests providing greater resistance than more open habitats (Stevens et al. 2004). Hence, realized isolation of wetlands is species-specific and highly dependent on movement behavior.

For semiaquatic species, the role of habitat heterogeneity is even more complicated. For pond-breeding amphibians with complex life cycles that include a terrestrial stage, the distribution and quality of upland habitat may be especially important (Marsh and Trenham 2001). The joint habitat quality of wetlands and adjacent uplands may determine habitat suitability and the spatial distribution of species.

As such, delineating habitat patches for a wetland metapopulation could require going beyond just identifying wetlands from a map.

Conservation Implications and Future Challenges

Despite these complexities, many of which are related to how we should integrate habitat heterogeneity into the area-isolation paradigm, the metapopulation concept has been influential for land managers. The recognition of potential metapopulation dynamics for wetland species has forced managers to think about biodiversity conservation and restoration at landscape and regional scales instead of at the scale of single wetlands. Metapopulation dynamics also highlight the importance of landscape connectivity and wetland-upland linkages. Future challenges for conservation of wetland species forming metapopulations include maintenance of adequate habitat quality and connectivity despite ongoing habitat loss, fragmentation, and disturbance to the terrestrial matrix. Some species might already be functioning as nonequilibrium metapopulations (Fig. 2) just waiting for dynamics to play out. Finally, interactions between climate change and metapopulation dynamics (Opdam and Wascher 2004) will be crucial to persistence of many wetland species. Increased frequency of disturbances from large weather events will increase the temporal variability of wetland quality, and conservation of connectivity will be critical for facilitating shifts in geographic ranges.

Riparian Buffer Zone for Wetlands

21

Maohua Ma

Contents

Abstract

Riparian buffer zone is an ecotone located between human-disturbed lands and wetlands, lakes, or rivers. The main functions of the riparian buffer zone is to protect wetland ecosystem through flooding control, water protection, soil conservation, habitat provision for wild species diversity, and the influence they have on ecosystem processes in wetlands. Width and vegetation composition of riparian buffer zone are the key features that enhance its functions essential to establishing and maintaining healthy wetlands. To achieve a sustainable buffering

Introduction

Definition

The word "riparian" is derived from Latin word "ripa," meaning river bank. One of the accepted definitions was termed by Lowrance et al. (1985): "Riparian ecosystems are the complex assemblage of organisms and their environment existing adjacent to and near flowing water." A simple definition comes from Malanson (1993): "the ecosystems adjacent to the river." In wetland ecosystems, a riparian buffer zone is the interface located between human-disturbed lands (agricultural or industrial areas) and wetlands, lakes, or rivers (Figs. 1 and 2). Vegetation-covered habitats and communities along the river margins and banks are called riparian vegetation.

The riparian buffer zone along the water bodies provides more than just a beautiful landscape. The main ecosystem function of the riparian strip is to protect wetlands (Gregory et al. 1991). The riparian zones are also significant in ecology, environmental management, and civil engineering because of their roles in water protection, soil conservation, wild species diversity, and the influence they have on ecosystem processes in wetlands (Castelle et al. 1992). Vegetation in the buffer zones is important for its function to protect from leaked agrochemicals and eroded soil (Jenssen et al. 1994). The buffer zones also provide important habitats for animal species (e.g., butterflies, bees, birds) in wetland ecosystems (Forman 1995). In some regions, the terms riparian woodland, riparian forest, riparian boundary/margin, or riparian strip are used to characterize a riparian buffer zone (Fig. 3).

Background

Riparian buffer zones begam to be used for wetland protection and restoration only from last century when humans realized the ecological importance of wetlands and negative impacts of human activities on the wetlands. Since early civilization, many cultures have learned to live in harmony with wetlands and have benefited economically from surrounding wetlands, whereas other cultures quickly drained the landscape (Dugan 1993). The propensity in Eastern civilizations, e.g., the ancient Babylonians, Chinese, Egyptians, and the Aztec, was not to drain the landscape, as is frequently done in the West, but to work within the aquatic landscape, albeit often in a heavily managed way. In the West, since wetlands were considered as disastrous realms, sources of disease, and trackless wasteland, wetlands were drained and filled so that people could build on them, grow crops on them, and build roads across them

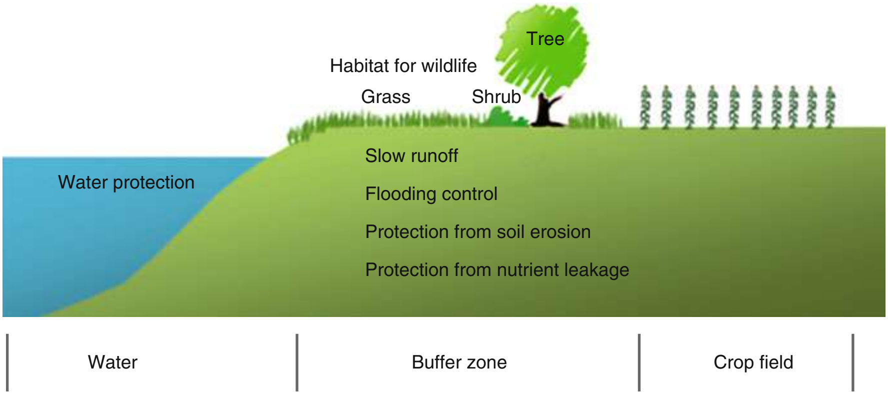

Fig. 1 Cross section of riparian buffer zone and its main functions

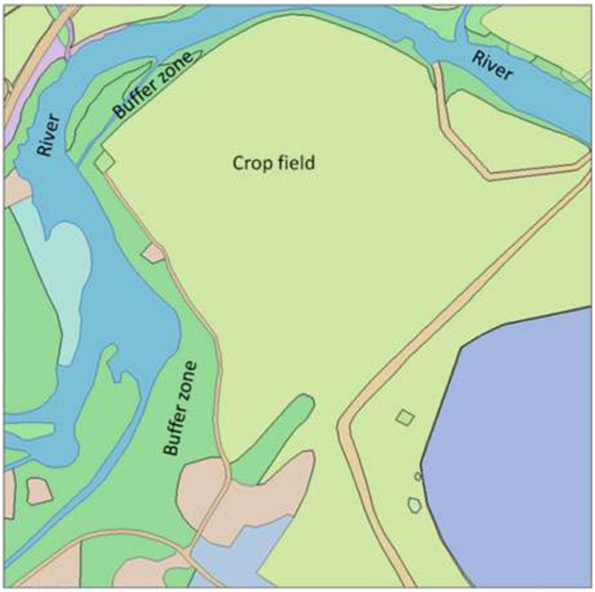
Fig. 2 A GIS map of a typical land mosaic composed of a river, buffer zone and crop field in a watershed agricultural landscape, southern Finland



(Mitsch and Gosselink 2007). No matter in the East and the West, heavy utilization, strong disturbances from human activities, drainage, and destruction of wetlands have caused rapid degradation and loss of wetland ecosystem (Mitsch and Gosselink 2007).

Starting in the 1970s, we became aware of the value and importance of wetlands and that they were disappearing. The Ramsar Convention is an international treaty signed in Ramsar, Iran, for conservation and wise use of wetlands (www.ramsar.org). The agreement was signed on February 2, 1971, and came into force from December 21, 1975 (Mattews 1993). It is one of the oldest specific conventions that deal not

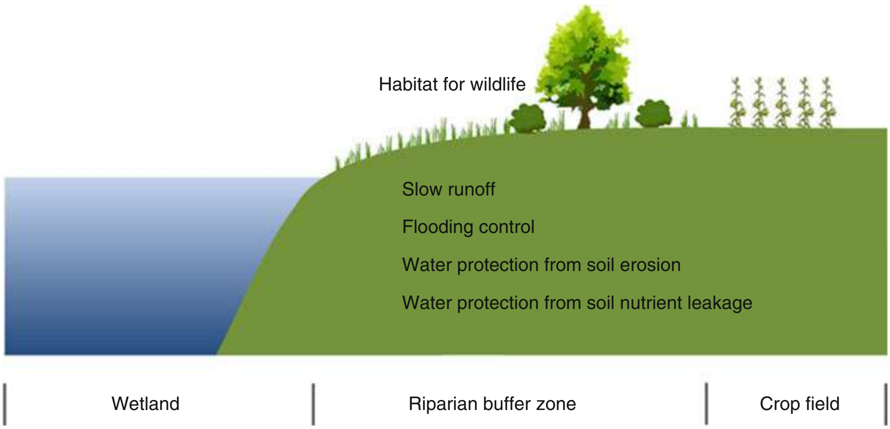


Fig. 3 Habitat in riparian buffer zone and wetland protection

only with the conservation of the wetlands but also its wise use (Ramsar Convention Secretariat 2010).

Wetland protection depends not only on managing wetlands themselves, but also on managing the surrounding water sources and landscape, above all in buffer areas. An abundance of scientific research published since the 1970s documents the value of establishing, maintaining, and enhancing vegetated buffers along wetlands. Wetland buffers provide important benefits including water quality improvement, stream-bank stabilization, flood control, wildlife habitat, and groundwater recharge (Castelle et al. 1992; Correll 1996; Wenger and Fowler 2000; USDA 2003). Wetland buffers also provide significant social and economic benefits by improving aesthetics and increasing property values (Lovell and Sullivan 2005; Qiu et al. 2006). For instance, the excessive nitrate-nitrogen flowing from Midwestern USA is exacerbated by the excessive drainage of the upper Mississippi River Basin that causes waters to leave the fertilized farmland quickly and immediately be transported to the Gulf of Mexico. The control of the nutrient leaching is important in the Gulf of Mexico because the continental shelf fishery in the Gulf is approximately 25% of the USA total. It has been suggested that restored riparian buffers would be necessary to provide enough denitrification to substantially reduce the nitrogen entering the Gulf of Mexico (Mitsch et al. 2001).

Roles and Functions

Water Protection

Wetland buffers improve water quality by trapping and/or transforming pollutants such as sediments, nutrients, pathogens, and pesticides in surface water via biofiltration. The meandering curves along water ways, combined with vegetation and root systems, dissipate stream energy, which results in less soil erosion and a reduction in flood damage. Surface runoff is slowed by buffer vegetation, causing larger sediment particles and pollutants adsorbed to sediment particles to settle out (Lee et al. 2003). This filtering function is greatly enhanced as the density of ground layer vegetation and the width of a buffer increase.

Flooding Control

Wetland buffers that are vegetated with trees and shrubs in floodplains greatly help to slow, store, and gradually release flood waters. Dense vegetation in a wetland buffer increases surface roughness of a floodplain and slows the velocity of overland flow while promoting shallow groundwater recharge, surface storage, and subsequent uptake of water by vegetation (Naiman et al. 2005).

Groundwater Storage

During dry periods, the water in rivers and wetlands may come solely from groundwater which is recharged in upland buffers. Vegetated wetland buffer areas help to slow surface runoff and promote infiltration thereby helping to maintain groundwater levels (Naiman et al. 2005). Elevated groundwater then discharges into streams to provide baseflow. They provide native landscape irrigation by extending seasonal or perennial flows of water.

Habitat for Wild Species

The riparian zones also provide habitats and corridors for wildlife, increase biodiversity, and enabling aquatic and riparian organisms to move along river systems avoiding isolated communities. They can provide forage for wildlife and livestock (Semlitsch and Bodie 2003). In addition, the strong, thick roots of trees and/or shrubs growing along the edge of a stream channel greatly increase the stability of the stream banks and can effectively promote soil biodiversity.

Recreation and Aesthetic

From a social viewpoint, riparian buffer zones provide nearby property values through amenity and views. Wetland buffers offer recreational, aesthetic, economic, and educational opportunities for neighborhoods and schools, promoting healthy lifestyles and enhanced community stewardship and relationships (Qiu et al. 2006). Riparian sports may include walking, running, biking, fishing, swimming, and boating.

Designing Buffer Zones

Width and vegetation composition of buffer zones are key features that enhance many functions essential to establishing and maintaining healthy wetlands.

Width

Width of buffer zone may be the most important factor in affecting buffering functions. Buffer zones are usually not wide enough to function in protecting water, especially in agricultural area. The recommended width of the buffer strip depends on many factors including slope, soil type, farming practices, size of crop fields, and the landowner's objectives. For instance, to remove chemicals and sediment from surface and subsurface runoff, buffer strips should be at least 20 m wide on each side of the waterway. A buffer strip less than 20 m wide does not hold water in the root zone long enough for chemicals to be removed from the water, although it can trap most sediment moving in surface runoff (Semlitsch and Bodie 2003).

However, the weakness of a fixed-width approach is that the buffer widths are not necessarily tailored to the specific conditions of and around the individual wetlands. Variable-width buffer approaches allow buffer area widths to vary according to site-specific or reach-specific conditions such as slope, soil condition, vegetative condition of the stream, or intensity of the existing land use. Typically with these approaches, a minimum buffer width is established that applies to all wetlands and then widths are widened based on site- or reach-specific conditions. The benefit of this approach is that the buffer area can incorporate protection for other sensitive natural features such as floodplains, wildlife habitat, and steep slopes.

Vegetation Types

The most effective riparian buffer zone normally has three zones of vegetation. This combination of trees, shrubs, and grasses helps protect the stream more than planting a single species. Trees and shrubs provide perennial root systems and long-term nutrient storage close to the stream. The warm season grass provides the highest density of stems to slow surface runoff from adjacent fields. The design can be modified to fit the landscape and the landowner's needs, for example, by replacing shrubs with more trees, substituting some of the trees with shrubs, or expanding the grass zone.

Maintaining Buffer Zones

Buffer zones must be monitored and managed to maintain their maximum water quality improvement. Trees and shrubs should be planted in early spring (between March and May, depending on the region) for the best performance of buffering function. Weed control is essential for survival and rapid growth of trees and shrubs in a buffer strip. However, since some types of weeds may provide proper habitats for wild species, maintaining buffer zones shall be also based on main benefits the buffer zones provide.

Conclusions and Future Directions

Scientific studies provide extensive evidence that buffer zone is an important tool for achieving wetland protection. Buffer zone planning shall depend on the individual target for wetland protection. For water quality benefits, buffers need vegetation to slow runoff and for groundwater to pass through and undergo pollutant removal. For flood control, a wide buffer should try to maximize available space in the floodplain so as to increase short-term water storage, and vegetated banks should be present to stabilize stream banks. For habitats, buffers shall be covered by native vegetation of a variety of strata, providing connectivity to other patches, and with minimal disturbances. For overall ecosystem purposes, buffers are most effective when they provide leaf litter to supply the food chain, canopy for shade, large woody debris for in-stream cover, and a place for groundwater recharge which in turn supports baseflow in the stream.

To achieve a sustainable buffering function for wetlands, careful multidisciplinary planning based on ecological knowledge and socioeconomic context is necessary at landscape scale (Wells and Brandon 1993). It is at the landscape scale that we shall continue to understand the relationships between buffer zones and landscape-level management. Increasing landscape heterogeneity can increase size of species pool, which may promote species diversity and vegetation density in buffer zones. A range of socioeconomic policies is needed for farmers to establish, manage, or maintain wider buffer zones and diversified landuse. For instance, the EU-level envrionmental legislation, the agro-environmental scheme, includes the establishment of riparian buffer zone (EU-Commission 2000). In Finland, the national-level agro-environmental scheme includes compulsory measures stating that buffer zones along rivers or lake or sea shores must be at least of 3 m wide, and the regulation also financially encourages farmers to apply on average at least of 15 m wide buffer zone along waters. In the future, a landscape-based approach integrating with policy, economic, and ecological aspects of wetland ecosystem composing of waters, buffers, fields, and other types of landuse is needed.

Source-Sink Dynamics of Wetlands

22

Tracy A. G. Rittenhouse and William E. Peterman

Contents

Abstract

Source-sink dynamics stem from metapopulation theory, where sources are populations with births exceeding deaths and emigration exceeding immigration, and sinks are populations with deaths exceeding births. Sink populations are sustained by immigration from nearby source populations, and thus functional connectivity among wetlands is key to maintaining source-sink dynamics among wetlands. The wood frog is an example pond-breeding amphibian where source-sink dynamics among wetlands is critical to regional population persistence. We summarize how source-sink dynamics can be inferred from demographics, genet-

Introduction

Definition

Source populations are characterized as having birth rates that exceed death rates and thus an increasing population. This positive growth leads to emigration from the population, and the rate of emigration in source populations exceeds the rate of immigration. As such, sources are net exporters of individuals into the system. In contrast, sink populations are net importers or receivers of dispersing individuals. Sink populations are further characterized as having death rates that exceed birth rates, which leads to population decline. As such, the existence of such sink populations is entirely dependent upon the contributions of dispersers from source populations.

Source-sink dynamics stem from metapopulation theory, which has provided a useful framework to address conservation questions, especially in light of increasing loss or alteration of habitat and fragmentation due to land use that can jeopardize the persistence of species (Hanski and Ovaskainen 2000; Urban et al. 2009). Pulliam (1988) provided the formal description of the demographic source-sink model. Sources are populations in high quality habitat with births exceeding deaths and emigration exceeding immigration. In contrast, sink populations generally exist in low quality habitat, where deaths exceed births, and the populations are sustained by immigration from surrounding source populations. In order for source-sink dynamics to be realized, there must be functional connectivity among habitat patches on the landscape to allow successful dispersal and rescue of sink patches or for colonization of new habitat patches. Functional connectivity is a result of species vagility, distance between habitat patches, and quality of the matrix between patches.

Wetlands provide vital breeding and foraging habitat for many species, but are particularly important for reptiles and amphibians. Pond-breeding amphibians are distributed patchily across the landscape and are frequently assumed to exhibit metapopulation dynamics, especially in fragmented landscapes that limit connectivity (Semlitsch 2008a). Metapopulations of pond breeding amphibians can be viewed from a “ponds-as-patches” perspective (Marsh and Trenham 2001; Richter-Boix et al. 2007). There are several factors that should be considered when characterizing amphibian populations in this manner. First, the pond should be defined to include both the aquatic breeding habitat and the immediate surrounding terrestrial core habitat (95% core area usually within 300 m) where the breeding adult population resides (Rittenhouse and Semlitsch 2007; Semlitsch 1998; Semlitsch and Bodie 2003). Second, several ponds that are in close proximity may function as a unit, and thus several ponds compose the patch or population. This possibility occurs when the amount of amphibian breeding activity at one pond influences the amount at a neighboring pond or when adults shift breeding effort among several adjacent ponds across years (Petranka et al. 2004; Pope et al. 2000). Third, this characterization may not be true in all situations; despite the fact that many amphibians breed in distinct patches, not all amphibian populations exist as metapopulations. For example, if there is extensive movement among all ponds, then these ponds likely constitute a single population (Smith and Green 2005).

Methods for Identifying Source-Sink Dynamics

In the strictest sense, source-sink dynamics requires estimation of birth, death, immigration, and emigration rates. Estimation of these rates presents logistical challenges. Estimates of population growth rates often require detailed, long-term population monitoring (e.g., mark-recapture, nest survival). Such approaches can be both time and cost prohibitive, making robust estimates of these parameters unfeasible in many circumstances. There can also be significant difficulty in identifying movement among populations as this often involves direct monitoring of individuals in space and time. These observations have traditionally been made using mark-recapture or radio telemetry (Gamble et al. 2006, 2007; Rittenhouse et al. 2009), which has generally limited the scope of inference to a few select populations. The increased accessibility of molecular methods is now allowing for direct quantification of movement among numerous populations. These genetic estimates represent a more complete picture of population connectedness as well as provide an estimate of realized dispersal resulting in successful reproduction (Wang et al. 2009).

Other approaches to assess population connectivity are based on resistance kernels (Compton et al. 2007; Wasserman et al. 2010), electric circuit theory (McRae et al. 2008), or graph theory (Urban et al. 2009). Each of these methods can assess the potential connectivity among populations as a function of distance and intervening habitat. When paired with demographic models of population size, reproduction rates, and dispersal kernels (Schick and Lindley 2007), graph-theoretic models can be used to identify source and sink populations on the landscape. Although potentially less informed and more reliant on model assumptions, these network models are less data intensive than empirical observations of movement, and less expensive than genetic approaches. Further, these models can provide a robust framework for assessing connectivity, directionality of movement among populations, as well as management effects on the network as a whole (e.g., effects of wetland loss or mitigation on connectivity and movement; Schick and Lindley

2007). Recently, Murphy et al. (2010) combined network-based gravity models with spatial population genetic data to infer functional connectivity.

Using Genetics to Infer Source-Sink Dynamics

Genetic estimates of connectivity may be simpler to obtain than direct observation of dispersing organisms, and they provide a means to assess population connectivity across generations. One potential limitation of these estimates is that they can reflect historical processes and may not be representative of current dispersal patterns (Pearse and Crandall 2004). Nonetheless, genetic data can allow for the estimation of parentage, effective population sizes, dispersal rates, and connectivity among populations, all of which can be used to infer source-sink dynamics (Manier and Arnold 2005; Martínez-Solano and González 2008; Peery et al. 2008). In a study of garter snakes (*Thamnophis elegans* and *T. sirtalis*) in California, Manier and Arnold (2005) found gene flow (i.e., dispersal) was asymmetric among the 23 populations studied, and that a few populations contributed a disproportionate number of dispersers to the metapopulation. Further, they found that genetic measures of effective population size and migration rates were often significantly different from those obtained through direct observation via mark-recapture. These findings underscore the potential power of genetic approaches and the difficulty in obtaining direct estimates of population vital rates. In another study, Martínez-Solano and González (2008) found that recently established populations of common toads (*Bufo bufo*) showed both genetic and demographic signatures of sink populations. Specifically, they had lower effective population sizes, had a greater of rate of immigration, and had greater frequency of heterozygotes than expected (heterozyote excess).

Network Models

Wood frogs (*Rana sylvatica*) are a widely distributed pond-breeding amphibian in North America. Extensive demographic and movement studies have been conducted on wood frogs (Berven 1990; Berven and Grudzien 1990; Rittenhouse et al. 2009), making them an ideal species for parameterizing demographic network models (Schick and Lindley 2007). Using 6 years of egg mass counts from 41 ponds in east-central Missouri, a demographic network model was parameterized to estimate: (1) number of metamorphic individuals produced at each pond, (2) the number of metamorph frogs that would reach maturity and return to their natal pond for reproduction, (3) the number of metamorph frogs that would reach maturity and successfully disperse to a new breeding pond, and (4) the ratio of immigrant to emigrant frogs at each pond (ratio >1 = source population, ratio <1 = sink population; Peterman et al. 2013). Parameters for survival, rates of dispersal, and dispersal distance were obtained from empirical estimates found in the literature (Berven 1990; Berven and Grudzien 1990). The average of the 6 years of observations is shown in Fig. 1. Being an average, this figure encompasses annual variation

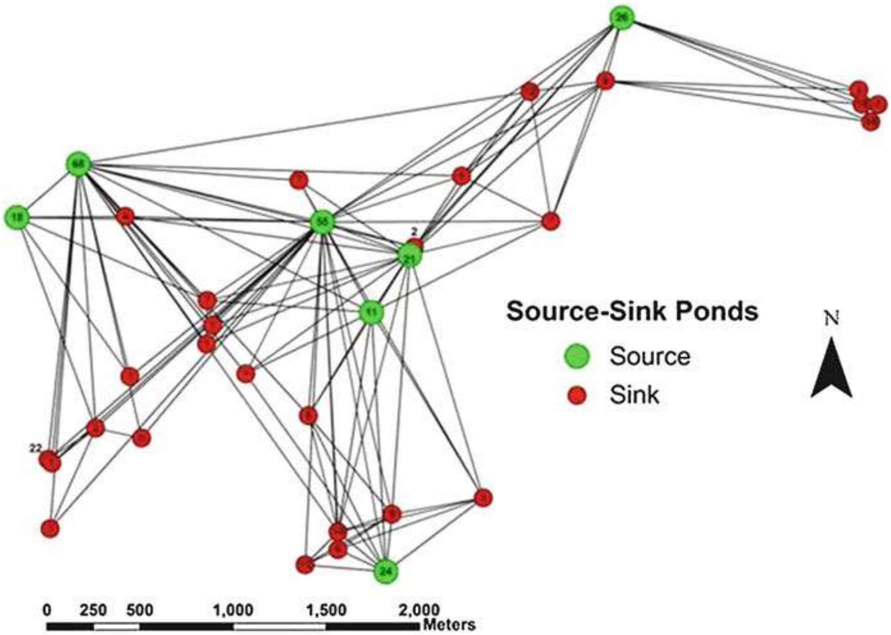

Fig. 1 A demographic network model of wood frog populations in east-central Missouri, USA. Each point represents the spatial location of a pond, and the numbers on each point represent the mean number of egg masses (equivalent to the number of breeding females) present at ponds from 2006 to 2010. Connectivity of ponds was determined as a function of distance and the number of potential dispersing juvenile frogs. Ponds with emigration rates greater than immigration rates were designated as sources

in reproductive success, which largely corresponded to variation in precipitation. This modeling approach, although simplistic and with many inherent assumptions, allows for spatial and temporal assessment of source-sink dynamics. Analyses similar to these could help inform future wetland mitigation to provide optimal placement of wetlands in relation to existing populations. Alternatively, if wetlands were to be lost or altered, these models could be used to minimize the damages to the connectivity of the metapopulation.

Future Directions and Challenges

As a specific case of meta-population dynamics, source-sink dynamics may be particularly relevant in the study of wetlands, which are often viewed as habitat patches in the context of the species using them (Marsh and Trenham 2001). Future management of wetlands should take into consideration connectivity among populations, but also recognize that all populations are not equal. By identifying source and sink populations within the metapopulation, ranked conservation or management priority can be given to assure that the most robust populations are conserved. For example the number of individuals that complete metamorphosis and successfully emigrate from a pond is an important factor to consider when developing management plans (Semlitsch 2000). Alternatively, isolated populations or perennial sink populations can be selectively targeted for conservation or restoration actions. Restoration of a wetland that is consistently a sink population (e.g., improper hydrology or presence of fish) has the potential to strengthen regional population persistence by increasing the number of source populations. If low connectivity due to low dispersal success is a concern, then restoration efforts may include the creation of new wetlands to serve as stepping stones (Petranka et al. 2007; Petranka and Holbrook 2006). An additional challenge to estimating connectivity using resistance kernels, circuit theory, or graph theory is determining the effects that land cover and landscape features have on dispersing individuals. Current assessments often rely on expert opinion, but this approach should be used with caution as Charney (2012) demonstrated that expert models performed poorly.

Source-sink dynamics are important processes to consider within the context of wetland mitigation, and a future challenge for wetland managers will be to incorporate source-sink dynamics into wetland mitigation (Keagy et al. 2005). Filling one wetland and creating a new wetland in an alternative location may result in an equal number of wetland acres, but functions are not often realized in mitigated wetlands (Semlitsch 2008b). If source populations are continually destroyed and mitigated with sink populations, species persistence on the landscape will be greatly affected. A pond's role in the metapopulation can be dependent on within ponds features such as hydrology and vegetation that affect productivity (Shulse et al. 2012), as well as placement on the landscape, which affects connectivity with other ponds and can influence the species community that colonize mitigated ponds (Shulse et al. 2010). Wetland mitigation will be more effective when taking into consideration demographic and life history characteristics of species.

A major challenge in conducting source-sink analyses has been, and will continue to be, the estimation of the necessary population parameters. Although technology for directly tracking individuals continues to improve, these methods are likely to remain costly and labor intensive. In contrast, genetic studies for non-model species are continuing to become more affordable. Genetic methods have limitations, but their use in studies of source-sink dynamics has the potential to provide the most complete picture of cryptic movement among populations. At the very least, genetic analyses can provide a starting point for identifying which populations warrant more intensive empirical studies of vital rates.

Contents

Abstract

Wetland landscapes and wetland watersheds are both general, flexible terms that are often used interchangeably; however, the boundaries of landscapes are less discrete than those of watersheds, which have specific drainage areas. In expansive flat topography, as in Florida and the US Upper Midwestern prairie pothole region, it is difficult to locate watershed boundaries, so the term landscape is more appropriate. Elsewhere, wetland catchments are easily defined, and it is useful to refer to watersheds whenever emphasizing the inseparable interactions between the water that flows downslope and collects to form wetlands. Here, we consider watersheds to be parts of larger landscapes, which we also call regions to emphasize their large spatial scale. Most of our examples are drawn from the USA, where we have the greatest experience.

Introduction

Wetland landscapes and wetland watersheds are both general, flexible terms that are often used interchangeably; however, the boundaries of landscapes are less discrete than those of watersheds, which have specific drainage areas. In expansive flat topography, as in Florida and the US Upper Midwestern prairie pothole region, it is difficult to locate watershed boundaries, so the term landscape is more appropriate. Elsewhere, wetland catchments are easily defined, and it is useful to refer to watersheds whenever emphasizing the inseparable interactions between the water that flows downslope and collects to form wetlands. Here, we consider watersheds to be parts of larger landscapes, which we also call regions to emphasize their large spatial scale. Most of our examples are drawn from USA, where we have the greatest experience.

Landscape-Scale Changes in Wetland Area

Extensive drainage, water diversions, and groundwater depletion eliminated over 100 million acres of wetland (53%) in the 48 contiguous states by the 1980s (Dahl 1990). In several states (e.g., California and the Upper Midwestern “corn belt”), over 80% of historical wetland area succumbed to drainage and oxidation of organic soils or to filling and development (Dahl 1990). Aldo Leopold (1949) vividly described the example of Central Wisconsin during the 1930s Dust Bowl years: “the marsh was gridironed with drainage canals, speckled with new fields and farmsteads. But crops were poor and beset by frost, to which the expensive ditches added an aftermath of debt. Farmers moved out. Peat beds dried, shrank, caught fire. . ..After a dry summer not even the winter snows could extinguish the smoldering marsh. . ..For a decade or two crops grew poorer, fires deeper, wood-fields larger, and cranes scarcer, year by year.” The historical wetland landscape was altered in irreversible ways.

Reductions in wetland area and the near-permanent loss of underlying peat create significant challenges for landscape-scale restoration, and most areas drained for agriculture have remained cultivated. Large projects have, however, been initiated to restore Kankakee Wetlands (Indiana), the San Francisco Bay Delta (California), the Everglades (Florida), and the Gulf of Mexico (notably in Louisiana). USA’s July 2012 RESTORE Act allocates billions of dollars in oil-spill penalties to BP toward restoration of Gulf Coast wetlands. Funds can support up to 109 projects included in Louisiana’s 50-year, $50 billion Coastal Master Plan. In addition, 80% of the Clean Water Act penalties will help implement a comprehensive plan for the Gulf Coast focused on ecosystem and coastal restoration, and 5% will support Gulf Coast research, science, and technology, including fisheries management, ecosystem monitoring, and a Gulf Coast Center of Excellence in each impacted state.

Regions and watersheds have individual “wetland profiles,” as revealed by large-scale analyses of wetland area and wetland resources. For example, Danz et al. (2007) characterized wetlands along the coasts (U.S. sides) of all five Great Lakes, based on 86 human-influenced stressors for each of 762 watershed-based units. Not surprisingly, the greatest environmental stress had accumulated in watersheds near centers of intensive land use and urbanization, namely, western L. Michigan, southwestern L. Erie, and southeastern L. Ontario. Subsequent analysis of biological responses indicated strong responses in water chemistry and fish, bird, and plant communities (Danz et al. 2007, Johnston et al. 2009). Among the vegetation responses, Frieswyk et al. (2008) demonstrated dominance by invasive cattails (*Typha angustifolia* and *T. x glauca*) at three spatial scales: individual wetlands, whole lakes, and the entire Great Lakes region (i.e., USA coasts). Wetland degradation was thus both direct (altered abiotic conditions) and indirect (invasions and lost species).

Wetland restoration efforts have typically focused on returning the amount of area lost and on efforts to establish native vegetation and attract native wildlife, without sufficient attention to wetland type or functions. The restoration of ecosystem services is now gaining prominence in restoration planning and implementation. Ecosystem services (functions that are valued by people) are often included in restoration goals, especially water quality improvement, flood abatement, and carbon storage (i.e., long-term sequestration).

Landscape-Scale Changes in Wetland Services

The Millenium Ecosystem Assessment (MEA 2005) classified ecosystem services as supporting (productivity, nutrient cycling), provisioning (e.g., timber production, gene pools that give rise to new foods and medicines), regulating (e.g., infiltrating runoff, abating flooding, improving water quality, storing carbon in peat), and cultural (esthetics, education, research, recreation). Within that assessment, biodiversity support was treated as encompassing all services, i.e., plants, animal, and micro-organisms (fungi, bacteria) were regarded as the key providers of wetland ecosystem services.

Even though wetlands typically comprise less than a quarter of a watershed's area, they provide disproportionately greater services (cf. data in Costanza et al. 1997). Losses in ecosystem services from the contiguous USA declined by approximately one-half after that mapped in the 1780s, but the associated loss of ecosystem services was not quantified until recently. Yet we receive occasional reminders of the historical services provided by large areas of wetland, such as flood abatement. The catastrophic flooding of the Mississippi River in 1993–1994 killed 50 people, wiped out levees, forced thousands of people to evacuate their homes for months, and caused $15 billion in damages; "The flood was unusual in the magnitude of the crests, the number of record crests, the large area impacted, and the length of the time the flood was an issue" (Larson 1996). Much was blamed on historical wetland loss; the restoration of just 3% of the floodplain may be able to prevent future catastrophic floods (Hey and Philippi 1995). The capacity of landscapes to abate flooding, clean the water, store carbon, and support biodiversity has clearly diminished as wetland area has declined, even though direct quantification of specific services is lacking. In fact, even today, historical losses and future gains are determined by hydrogeomorphic modeling (as in Miller et al. 2012), rather than direct measurement.

Attempts to reverse the degradation of landscapes by restoring wetlands to improve water quality, abate flooding, and sequester carbon requires careful attention to the location and type of wetlands to be restored and their basic hydrological conditions. The quantity of water available for restoration can either be too low (where water has been diverted or overconsumed) or too high (from runoff that fails to infiltrate upstream due to compacted soils and hardscapes). Watersheds produce excess runoff if they have undergone intensive land use for urbanization (and hard surfaces designed to shed, rather than infiltrate, water) and agriculture (which reduces soil structure and permeability and hence increase water discharge). In turn, excess water carries excess nutrients and other contaminants that further challenge wetland restoration at landscape scales. Nevertheless, Sweden embarked on an ambitious program of restoring 12,000 ha of wetlands (mostly shallow-water wetlands and ponds) within a large agricultural region. Large challenges catalyze landscape-scale restoration plans.

A surge in the construction of ponds between 1998 and 2004 in the conterminous USA (700,000 acres; Dahl 2006) led to a net gain in wetland area but did not compensate for continued losses of coastal and forested wetlands in their naturally occurring landscape positions. A pond cannot fully replace lost biodiversity or wetland ecosystem services performed by fens, bogs, marshes, meadows, and swamps. Given the serious consequences that follow large-scale loss and degradation of wetlands, the need for wetland restoration has never been greater. To regain lost services, NRC (2001) recommended restoring former wetlands, rather than creating wetlands, e.g., excavating ponds from uplands. NRC (2001) further proposed that restoration be done within a watershed context and following a strategic plan.

Watershed Planning for Strategic Wetland Restoration

Wetland restoration that is strategic at the watershed scale pays attention to location and wetland type (NRC 2001; Zedler 2003). For example, to compensate for wetland loss throughout the watershed, it is preferable to reduce contamination at the source (prevention) and filter and treat the water immediately downstream (via wetland restoration) than to rely solely on retention ponds at the bottom of the watershed (Fig. 1). Downstream retention does not compensate for a lack of preventive measures upstream. Landscape position and wetland type helped explain sixfold differences in the ability of hundreds of wetlands to remove nitrogen; those constructed in Sweden outperformed those in nearby Denmark (Ayala 1996). Large shallow-water wetlands with complex, vegetated shorelines removed more nitrogen and supported more wildlife than small deep ponds (Hansson et al. 2005).

Wetlands can restore water quality by removing sediments, nutrients, toxic contaminants, and pathogens, but not all the unwanted materials in water can be removed quickly or easily. Nitrogen (N) removal by bacteria, for example, requires the water to have anaerobic conditions in close proximity to aerobic conditions (as in shallow-water wetlands); then, denitrifying bacteria can convert ammonium to nitrates to harmless nitrogen gas. Given the extent of N-caused coastal eutrophication and large dead zones at the mouths of major rivers, it would seem that human

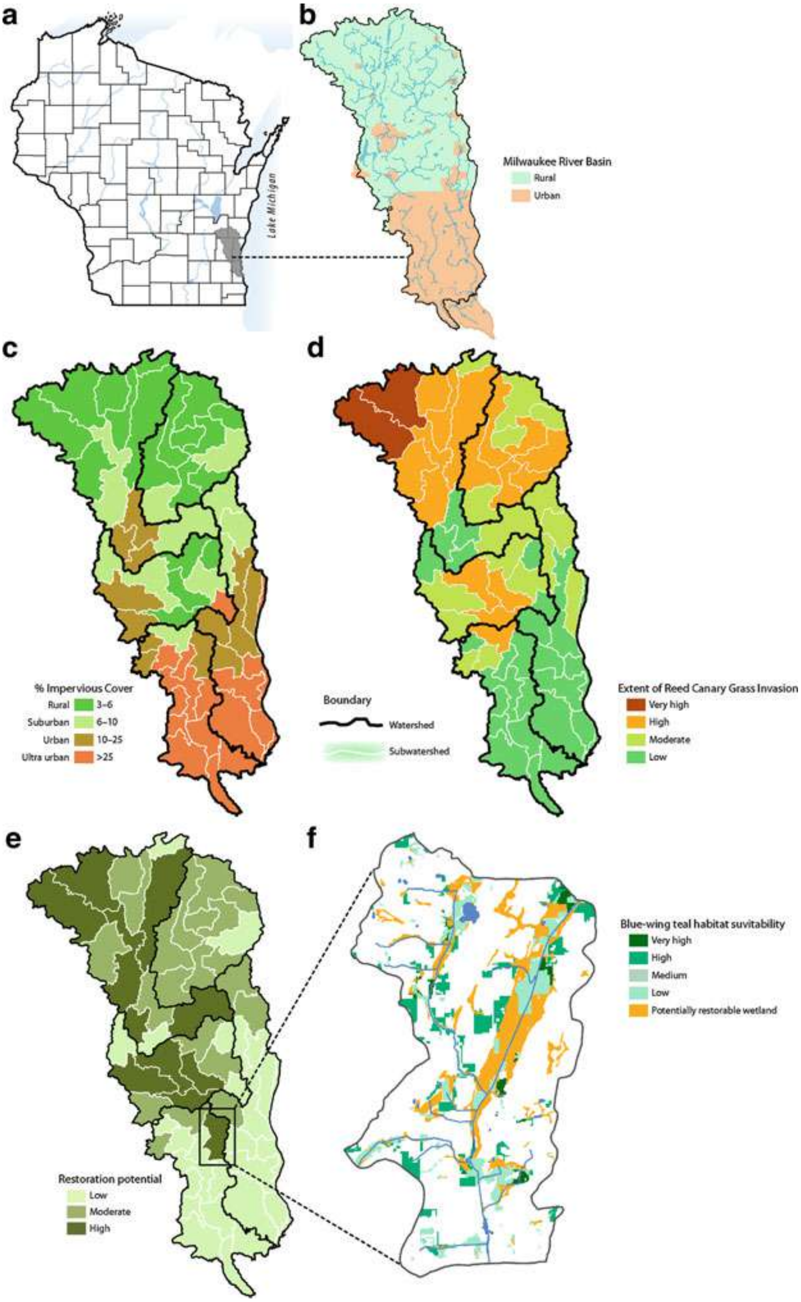

Fig. 1 Several attributes of the Milwaukee River Basin have been mapped by the Wisconsin Department of Natural Resources for use in watershed-scale planning for wetland restoration. The basin is located in eastern Wisconsin (1). The first basin-scale map (2) shows streams and municipalities. The percent area of impervious surfaces and classes of reed-canary-grass cover within the five 10-digit hydrological unit (HU) watersheds (2a) fed into an estimate of wetland

efforts to improve water quality would focus on N removal. Instead, efforts focus on phosphorus (P) reduction to reduce eutrophication in inland lakes, in part because P is more easily removed (Lewis and Wurtsbaugh 2008). Some P adheres to sediment particles and settles when water flows into deep ponds. P-removal is much simpler than N-removal; the latter relies on bacteria to denitrify large quantities of nitrates in shallow water where plant roots leak both organic matter (to fuel bacteria) and oxygen (for nitrification, the precursor to denitrification) (Paerl 2009).

Because P often enhances the growth of phytoplankton in lakes, the demands of swimmers, boaters, and fishers for water of high redundant quality have led to a focus on P removal. While retention ponds can accumulate P-rich sediment, and while the sediment can be excavated later and transported off site, such ponds do not make dirty water clean. Such ponds allow particulate contaminants to settle out during low-flow events (less so during major stormwater pulses). Because TSS and P removal are easily simulated in mathematical models, stormwater treatment systems are designed and built to meet specific sediment-removal standards. However, much of the N and dissolved contaminants flow through such systems. Because the actual performance of stormwater management facilities is rarely monitored, the shortcomings of retention ponds are poorly quantified (Pataki et al. 2011).

New landscape-scale tools, namely watershed plans, are becoming available to help decision-makers regain some of the lost services and to manage remaining resources (ELI and TNC 2014). Existing tools and plans span a spectrum from decision-making frameworks (e.g., Hruby et al. 2009) to prescribed outcomes for specific watersheds. Watershed plans can be tailored to regional needs and "allocate lands to their most suitable uses" (ASWM 2001). Because landscapes range from very dry (<0.3% of NV is wetland) to unusually wet (29.5% of FL is wetland) (Dahl 1990), the prioritization of types and locations of wetland restoration projects addresses varied challenges (Table 1).

Regulators (CoE 2008) adopted science-based advice to use a watershed approach in deciding where and how to restore wetlands to compensate for permitted losses (NRC 2001), except that wetland mitigation need not follow a watershed plan where there is none (Gardner et al. 2009). To implement watershed planning at the national scale would require funding to develop plans for model watersheds in all regions and coordinated efforts among agencies to fund wetland restoration, e.g., Fish and Wildlife Service, Natural Resources Conservation

Fig. 1 (continued) restoration "need" (= lost wetland/remaining wetland * % historical wetland). Opportunities for wetland restoration (3) were indicated as the relative area of potentially restorable wetlands within 12 digit HU subwatersheds. This map highlights the Little Menominee Subwatershed, where WDNR would like to increase Blue-wing Teal by restoring marsh and open water wetlands within a grassland matrix adjacent to the existing suitable habitat. Map 4 allows the user to visually evaluate where potential wetland restoration projects can best add to existing higher quality habitat (Maps courtesy of WDNR–Kate Barrett, Thomas Bernthal, Marsha Burzynski, Gary Casper, Joanne Kline, and Jeff Strobel)

Table 1 Examples of landscape-scale wetland restoration efforts

Priority ecosystem service	Large restoration program
Wetland diversity, especially endangered species	Kissimmee River (removing a flood control channel to restore the floodplain) and the Everglades (reducing eutrophication to reduce cattail invasions) (Toth 2010)
	Kankakee Sands, Indiana (>2,800 ha of hydrological modifications to restore plant communities) (http://www.nature.org/ourinitiatives/regions/northamerica/unitedstates/indiana/placesweprotect/kankakee-sands-project-office.xml)
	Southern CA coastal wetlands (restoring and sustaining tidal influence in multiple lagoons and salt marshes) (http://www.scwrp.org/)
Water quality in dead zones	Mississippi River (abating nitrogen in agricultural runoff in Iowa to protect the Gulf of Mexico) (Crumpton 2001)
	Restoring and creating 12,000 ha of wetlands in southwestern (agricultural) Sweden (Ayala 1996)
Environmental flows	San Francisco Bay Delta (less diversion of water to restore inflows, lower salinity, and sustain fish) (http://calwater.ca.gov/)
	Colorado River (restore flood pulses by managing the Glen Canyon Dam to restore multiple ecosystem services) (Lovich and Melis 2007)
Livelihoods based on fish and use of *Phragmites*	Mesopotamian Marshlands (restore water that was drained to exterminate Marsh Arabs). Large areas have been rewetted; *Phragmites* is once again widespread; rare teal are becoming abundant; Marsh Arabs are returning; fishing has resumed. Contaminated water and uncertain water supplies remain concerns (Alwash In press 2013; http://pdf.usaid.gov/pdf_docs/PDACF082.pdf)

Service, and many not-for-profit organizations. In fulfilling a landscape approach, decision-makers would include planning for all ecosystems, not just wetlands. To allow swapping of one type of wetland and its set of services for another, such as a pond, would require much better data on the values attributable to each wetland service. A further improvement would be the addition of economic profiles for regional wetlands including information on the specific ecosystem services provided by each wetland type. At present, economic valuations are inadequate (Aronson et al. 2010).

A Model Watershed Plan

The Duck-Pensaukee Watershed Approach (Miller et al. 2012) was developed for a 128,909 ha Great Lakes coastal watershed (8-digit US Geological Services hydrologic unit code [HUC]) by The Nature Conservancy in collaboration with Environmental Law Institute, Wisconsin DNR, St. Paul District of the Corps, and EPA

Region 5, tribes, counties, municipalities, conservation organizations, and academic researchers. The approach falls in the middle of the watershed planning spectrum (ELI and TNC 2014), as it evaluates and ranks conservation opportunities across the watershed but does not prescribe specific actions or outcomes. Instead, it enables users to match individual or collective restoration objectives (e.g., flood abatement, wildlife habitat, etc.) to subwatersheds and specific sites with the greatest likelihood of meeting those objectives. Unique features of the plan include: (1) a watershed profile to identify high priority subwatersheds, based on historical losses in services; (2) identification of specific sites with high potential to provide an array of ecosystem services; (3) a focus on wetland-upland connections important to wildlife; and (4) ability to tailor state Wildlife Action Plan priorities to a watershed scale and make them spatially explicit.

Users of the approach are first guided toward specific subwatersheds that have experienced the greatest decline in each of four ecosystem services: water quality improvement, flood abatement, surface water supply, and carbon storage. Declines in these services since the 1800s were determined by adapting the methods of the National Wetland Inventory-Plus (Tiner 2005), which correlate site characteristics (e.g., cover type, hydrogeomorphic features) with ecosystem services, for both historical and current wetland extent and condition. An index of change was then created for each of fifteen 12-digit HUCs (averaging 8,594 ha), enabling users to apply restoration efforts toward the subwatersheds with the greatest likelihood of returning ecosystem services.

After subwatersheds have been selected, individual sites can be chosen based on the relative potential to restore ecosystem services: water quality improvement, flood abatement, surface water supply, shoreline protection, carbon storage, and fish and wildlife habitat provision. Each potentially restorable wetland has been ranked for its ability to support a suite of priority and representative wildlife using the Wildlife Tool (Kline et al. 2006), which creates maps of probable habitat via expert-informed modeling. Sites have been further ranked for their potential to provide the remaining services by adapting the Wetland Evaluation Technique (WET) (Adamus et al. 1991), which calculates the probability of service provision based on a suite of criteria in three categories: opportunity, effectiveness, and social significance. For the example of water quality improvement, *opportunity* criteria included catchment attributes, such as impervious surfaces, land use, and nutrient sources. *Effectiveness* criteria included ecosystem characteristics of the site, such as persistent vegetation in depressions that could slow floodwaters and settle solids. *Social significance* criteria focused on the site's ability to benefit society (Figs. 2 and 3).

The Duck-Pensaukee Watershed Approach is a pilot effort designed to be applied in other watersheds, given the availability of data and technical personnel. Once components of this plan are implemented, the monitoring of outcomes, such as water quality at strategic locations, will serve both science and practice. Additional knowledge would accrue if subwatersheds were paired (with and without restoration efforts) or if several subwatersheds with varying amounts of restored wetland were compared as direct tests of the effectiveness of restoration at the landscape scale.

Fig. 2 A floodplain of the Pecatonica River in southwest Wisconsin, restored by the Wisconsin Department of Natural Resources and The Nature Conservancy. The stream segment was cleared of brush and sediments that had eroded from agricultural fields (**a**), with rich topsoil stockpiled on site and removed voluntarily when advertised as free for the taking. The creek bed was left intact, intended for fish use, and bare banks were stabilized using mulch-matting (**b**). A cover crop and native species were sown on the new floodplain, and woody debris was added to enhance fish habitat (**c**). Additional restoration took place upstream when the site and funding became available (October 2006 photos by J. Zedler)

Future Challenges

Now that watershed planning is underway, the challenge is to implement wetland restoration in ways that improve both the science and practice of wetland restoration. A landscape designed to maximize wetland services (e.g., support biodiversity, abate flooding, sustain clean water, and store carbon) would have at least these components:

1. Remnant wetlands left intact, buffered, and protected from damaging inflows (although "dry deposition" of airborne N and dust would still occur).
2. Wetlands restored in strategic locations to provide the above services.
3. Sufficient habitat patches with sufficient connectivity to support dispersal of plants and animals across landscapes as they respond to climate changes (cf. Vos et al. 2010).

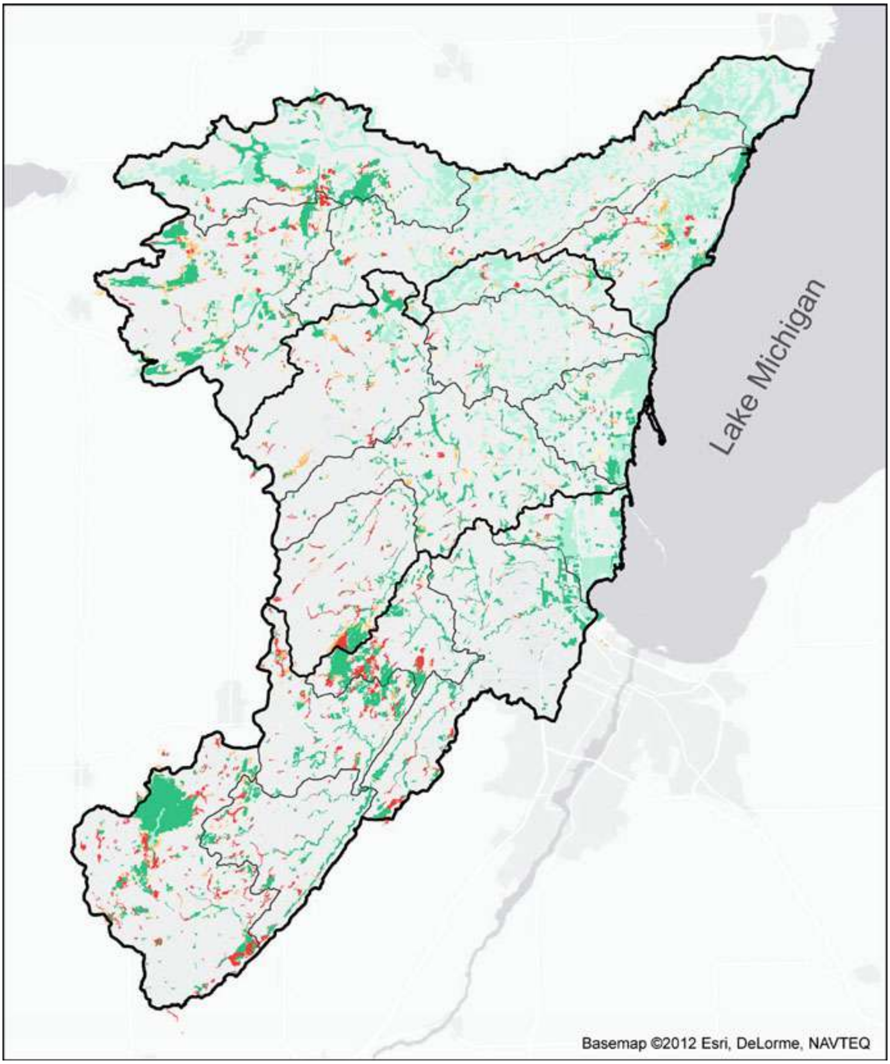

Fig. 3 Relative potential for wetland sites to improve water quality in the Duck-Pensaukee Watershed, Wisconsin, based on an assessment of watershed position, land-use context, and site characteristics. Darker shades indicate greater potential. Potential restoration sites (former wetlands) are indicated in *red* and existing wetlands are indicated in *green*

4. A populace dedicated to minimizing the discharge of water and contaminants, i.e., increasing infiltration (porous asphalt driveways, rain gardens, rain barrels), minimizing the use of pesticides and fertilizers, and practicing no-till agriculture and crop rotation (with N-fixing legumes) wherever possible. Reducing runoff and minimizing the contaminant loads upstream would reduce the workload for downstream wetlands.

5. Paired subwatersheds that compare landscapes with and without restored wetlands.
6. Broad upland buffers (free of cultivation, grazing and urbanization) would surround wetlands and reduce contamination.
7. Where wetland protection and restoration are no longer able to provide necessary ecosystem services, stormwater management facilities (constructed from uplands) would collect runoff from agricultural fields and urban developments, use native vegetation to stabilize exposed sediment, and remove both N and P, as well as other contaminants.

Wetland restoration is poised to improve ecosystem services at both site and watershed scales. Recent comparisons of watersheds in North Carolina indicate large discharges of N and P with only small losses of wetland area (Flanagan and Richardson 2010). It follows that small gains in wetland area could measurably improve nutrient removal, especially if projects are located strategically and implemented skillfully, following a watershed plan. At the same time, services that are compatible with nutrient removal would be augmented; potential examples are flood abatement (via slowing water flow and enhancing infiltration) and carbon storage (via burial of organic matter under sediments).

Wetland Heterogeneity

24

Daniel J. Larkin

Contents

Abstract

Heterogeneity is a key feature of wetland ecosystems, which vary physically, chemically, and biologically over space and time. Today, longstanding interest in how heterogeneity influences fundamental ecological processes is coupled with concern that anthropogenic changes are reducing the heterogeneity of wetland and other ecosystems. Spatial heterogeneity is apparent in wetlands at landscape, habitat, and micro scales. Variation can be gradual along environmental gradients or abrupt; even relatively small changes in wetlands can exert large influences through interactions with hydrology. Temporal heterogeneity is an important feature of wetlands, from the decadal or longer scales associated with vegetation succession to diurnal variability in water levels. Origins, effects, and applications of heterogeneity to wetland management are discussed, with a focus on the spatial dimension of wetland heterogeneity at the habitat scale.

Introduction

Heterogeneity is a broad concept used to describe one of the key features of wetland ecosystems: their variability in structure and function over space and/or time. Ecologists have a longstanding interest in understanding how spatial variability influences the distribution of organisms, interactions among species, and community change through time. Today, this interest is coupled with widespread concern that anthropogenic global change is reducing the heterogeneity (i.e., the ecological distinctiveness) of the planet's ecosystems (McKinney and Lockwood 1999).

Wetland heterogeneity occurs across multiple dimensions and scales. At the landscape scale, there is heterogeneity in the types of wetland habitats that occur in a region (Fig. 1a). For example, a northern-temperate landscape may be dotted with marsh, sedge-meadow, fen, shrub-carr, and bog systems that vary in size, density, and proximity. At the habitat scale, wetlands are heterogeneous over two-dimensional space, e.g., in the interspersion of vegetation with open water, bare ground, and other cover types (Fig. 1b). This change can be gradual along environmental gradients (Squires and van der Valk 1992) or abrupt, as when interactions between organisms and their environments create sharp boundaries (Pennings and Callaway 1992). A third spatial dimension is vertical heterogeneity.

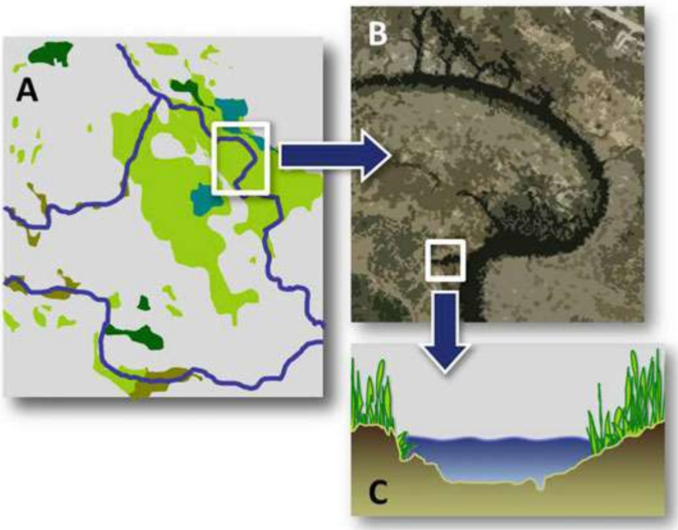

Fig. 1 Spatial heterogeneity influences wetland structure and function at multiple scales. (**a**) Diversity of wetland types (different-colored patches) imparts landscape-scale heterogeneity. (**b**) Within a wetland, changes in plant-community composition and water-vegetation interspersion are key components of habitat heterogeneity. (**c**) Topographic heterogeneity, depicted in this cross-section of a creek channel, provides distinct microenvironments

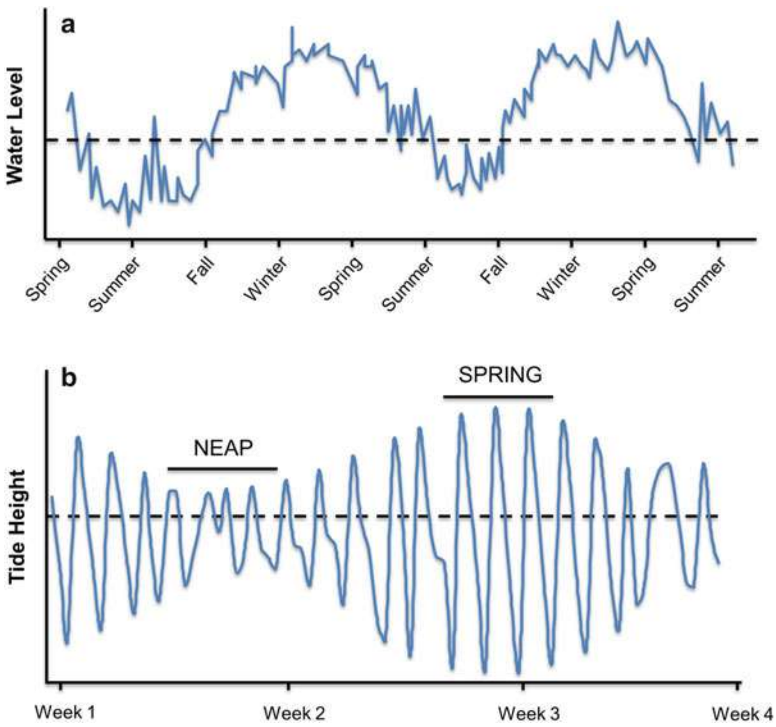

Fig. 2 Wetlands are strongly influenced by temporal heterogeneity. (**a**) In this hypothetical hydrograph of an inland, temperate wetland, the growing season spans from spring flooding to a mid-summer drawdown to fall flooding (elevation of the marsh surface shown with a dashed line). (**b**) Inundation of tidal wetlands changes frequently and predictably. Water depth varies on diurnal (high and low tides), lunar (spring and neap tides), and seasonal cycles (periods of overall higher vs. lower high tides)

Although wetlands lack the dramatic elevational changes of many terrestrial ecosystems, subtle differences in topography can be important features. Through mediation of wetland hydrology and edaphic conditions, such topographic heterogeneity (Fig. 1c) can greatly influence wetland structure and function (Larkin et al. 2006). Change over time is a fourth dimension of heterogeneity. Temporal heterogeneity includes the multidecadal scales associated with vegetation succession; interannual changes in weather and hydrology; seasonal differences in temperature, precipitation, and biotic activity; and diurnal variability in water levels and tidal inundation (Fig. 2).

The following sections introduce aspects of the origins, effects, and research and management challenges associated with wetland heterogeneity, with a focus on the spatial dimension of wetland heterogeneity at the habitat scale.

Sources of Heterogeneity

Spatial heterogeneity arises from geomorphological, hydrological, and biotic processes – and their interactions – and is a defining feature of certain wetland types. In coastal wetlands, tidal flows alter patterns of sediment distribution, creating complex tidal-creek networks (Williams et al. 2002). Movement of water also strongly influences the structure of riverine wetlands (Brinson 1993). Hummocks formed by *Sphagnum* mosses in peatlands can impede perpendicular water flow, yielding "flark-and-string" patterning over large spatial scales (Swanson and Grigal 1988). In salt marshes, waterlogging and salinity stress plants, altering the balance between competition and facilitation in ways that can cause stark zonation of dominant vegetation (Bertness 1991; Pennings and Callaway 1992). The sedge *Carex stricta* engineers ecosystems; its growth form produces complexes of elevated tussocks hosting numerous other plant species, interspersed with lower, often unvegetated inter-tussock spaces (Werner and Zedler 2002; Crain and Bertness 2005).

Effects of Heterogeneity

As in other ecosystem types, habitat heterogeneity of wetlands exerts strong effects on environmental/community structure and ecosystem functioning. In both natural and experimental systems, heterogeneity in wetland topography/hydroperiod has been shown to increase plant diversity (Vivian-Smith 1997). In a study of isolated wetlands in Germany, hydroperiod heterogeneity explained plant diversity better than the classic habitat-area relationship (Brose 2001). In Atlantic USA coastal wetlands, declines in macroinvertebrate diversity and fish-support functions accompanied the loss of marsh-surface heterogeneity that followed *Phragmites australis* (common reed) invasion (Angradi et al. 2001; Able et al. 2003). Abundance of several secretive marsh bird species (American Bittern, Least Bittern, Sora Rail, and Virginia Rail) was best predicted by interspersion of water and vegetation in a New York study, indicating that managing for complex spatial patterning could be beneficial for wetland-dependent birds (Rehm and Baldassarre 2007).

In addition to these effects on plant and animal communities, heterogeneity can also influence ecosystem functioning of wetlands. Wetland functions include valuable ecosystem services, such as carbon sequestration and denitrification. These and other biogeochemical processes in wetlands exhibit "hot spots and hot moments" (i.e., unusually high reaction rates in discrete patches or periods of time) (McClain et al. 2003) driven by spatial and temporal heterogeneity. Consideration of how hydrology, topography, and substrate and nutrient availability interact to produce heterogeneity in ecosystem processes can improve predictive models and facilitate targeting for specific ecosystem services (McClain et al. 2003; Wolf et al. 2011).

Future Challenges

While there has been substantial progress in understanding the effects of wetland heterogeneity, key challenges remain pertaining to its science and management applications. In some cases, the momentum to incorporate heterogeneity into restoration practice has outpaced its scientific justification, leading to high costs and poor outcomes (Palmer 2009). Further research is needed to separate the effects of habitat heterogeneity itself from potentially confounding factors like habitat area or the rarity of a given habitat within a landscape (Palmer 2009).

A key avenue for advancing the science of wetland heterogeneity is more rigorous testing of the effects of heterogeneity in restoration contexts. Recent work indicates that increased heterogeneity can enhance species diversity, food-web functions, and water-quality services in restored wetlands (Able et al. 2003; Larkin et al. 2008; Wolf et al. 2011). Wetland scientists and managers have a growing capacity to restore key components of habitat heterogeneity, e.g., through an improved understanding of how to restore for hydrogeomorphic complexity (Williams et al. 2002) or to jumpstart the work of facilitative ecosystem engineers like *Carex stricta* or *Triglochin maritima* (seaside arrowgrass) (Fogel et al. 2004; Lawrence and Zedler 2011). But the long-term effectiveness of these and other approaches employing hydrologic and biotic feedbacks to create and maintain heterogeneity in wetlands is not well known. More work is needed to critically evaluate the long-term trajectories of restored heterogeneity, the influence of heterogeneity across broader suites of taxa and desired functions, and its sustainability in the face of widespread watershed degradation that is having homogenizing effects on wetland environments and biota.

Landscape Genetics: Wetlands

25

Stephen F. Spear

Contents

Abstract

Landscape genetics is defined as research that explicitly quantifies how landscape variables (such as configuration and matrix quality) affect patterns of genetic variation and gene flow. Landscape genetic questions are typically focused on recent gene flow and landscape changes, and therefore, landscape genetic studies are often used to address ecological and conservation questions (e.g., barriers and corridors, source-sink dynamics, influence of landscape change) that are difficult to answer with more traditional demographic methods. Landscape genetics uses genetic data as the dependent variable and typically attempts to correlate genetic relationships with several independent variables representing landscape or environmental data, usually from a geographical information systems (GIS) computer environment that allows the landscape data to be visualized and analyzed using spatial statistics.

Introduction

Landscape genetics is defined as research that explicitly quantifies how landscape variables (such as configuration and matrix quality) affect patterns of genetic variation and gene flow (Storfer et al. 2007). Landscape genetic questions are typically focused on recent gene flow and landscape changes, and therefore, landscape genetic studies are often used to address ecological and conservation questions (e.g., barriers and corridors, source-sink dynamics, influence of landscape change) that are difficult to answer with more traditional demographic methods. Landscape genetics uses genetic data as the dependent variable and typically attempts to correlate genetic relationships with several independent variables representing landscape or environmental data, usually from a Geographical Information Systems (GIS) computer environment that allows the landscape data to be visualized and analyzed using spatial statistics.

The term "landscape genetics" was first coined by Manel et al. (2003) and was in response to advances in technology in both population genetics and landscape ecology that resulted in the availability of high resolution genetic and landscape data at a relatively low cost. These advances allowed researchers to be able to examine how contemporary genetic structure was affected by both natural and anthropogenic landscape features. A few studies had addressed landscape genetic questions before 2003 (without using that term), but the number of publications in the field began to rapidly increase after 2005 (Storfer et al. 2010), resulting in many empirical studies, another major review paper (Storfer et al. 2007), and special issues devoted to landscape genetics in journals such as *Landscape Ecology*, *Molecular Ecology*, and *Conservation Genetics*.

Organisms inhabiting wetland systems in a variety of environments have been the focus of several landscape genetic studies and have provided much insight into the ecology and connectivity of wetland systems. Wetlands serve as excellent study systems for landscape genetics because they can be easily modeled as patches that are connected by paths along which environmental variables are measured. This allows for traditional population genetic analyses to be melded with landscape data. Furthermore, many wetland organisms are limited by environmental factors due to their reliance on the discrete habitat type that many wetlands represent, and therefore, genetic variation is highly correlated with the surrounding environment. Wetland organisms that have been modeled in a landscape genetic framework include zooplankton (Michels et al. 2001), frogs (Murphy et al. 2010a, b; Goldberg and Waits 2010), salamanders (Spear et al. 2005; Giordano et al. 2007), turtles (Mockford et al. 2007; Howeth et al. 2008), snails (Wilmer et al. 2008), and fish (Dominguez-Dominguez et al. 2007). Of these taxa, amphibian species have been most widely studied, and there is a noticeable lack of studies investigating wetland plant species.

Estimating Genetic Diversity and Connectivity

Genetic diversity and connectivity in landscape genetic studies is most often assessed using microsatellite DNA markers, although SNPs are a future direction (Storfer et al. 2010). Microsatellites are noncoding regions of the genome characterized by multiple base pair repeats and are thus measured by the length of the repeat region (Fig. 1). Because they represent noncoding sections of DNA, they are not under natural selection and are thus considered neutral genetic markers (Schlötterer 2000). **Neutral markers** allow for inference of gene flow between sites because they are only subject to **genetic drift** and not the potentially homogenizing force of natural selection. Microsatellites typically mutate rapidly and it is thought this is likely due to misalignment of repeat sequences during DNA replication; such "slippage" generates additional repeat units (Schlötterer 2000). Therefore, microsatellites tend to have many alleles (or different forms of a gene), which make them ideal for assessing changes in genetic variation due to recent events. A SNP is characterized by variation in a single nucleotide and therefore can have at most four alleles. However, thousands of SNPs can be identified across the genome, and therefore, using SNPs can provide a better representation of what factors are influencing the entire genome (Kohn et al. 2006). Despite this, broad-scale SNP markers have only been developed for a few nonmodel species, and at the current time, microsatellites are still the most common marker used in landscape genetic studies.

Regardless of the genetic marker used, the raw data consists of a genotype (the identity of the specific alleles for each individual). With neutral markers, the specific genotype is not informative independently; rather investigators are interested in how that genotype relates to other individuals' genotype. In the case of wetland species, individuals are often clustered together, and a method that summarizes the genetic data across populations is typically used. The summary measure can either represent the genetic diversity within a single population or the genetic distance between two populations. Genetic diversity can be represented by metrics such as number of alleles or average **heterozygosity**. In landscape genetics, genetic diversity would be correlated with at-site environmental variables. Far more common in landscape genetics is to correlate genetic distances with among-site landscape variables. There are many types of genetic distances that can be estimated, the assumptions of which are beyond the scope of this article. However, in landscape genetics,

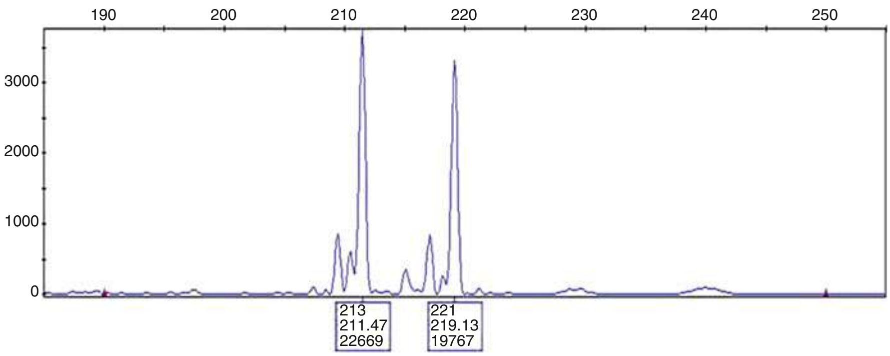

Fig. 1 Visualization of a microsatellite genotype. Each labeled peak represents a unique microsatellite allele that is distinguished by the length of the genetic fragment. Labels represent the number of base pairs and can be used to infer number of repeat units

popular types of genetic distances include F_{ST}, chord distance, Nei's distance, and proportion of shared alleles (Storfer et al. 2010).

Modeling Landscape Connectivity

One of the most important decisions when developing a landscape genetics study is how to model the landscape so as to represent the pattern of how genetic connectivity occurs across the landscape. This essentially is comparable to developing a hypothesis of landscape influence on genetic structure and then modeling that hypothesis. There are three approaches that so far have been most commonly used for identifying landscape influence on genetic connectivity. One method is to create a straight-line network among sites (connecting either all sites or a subset of sites), and values of landscape variables along this network are correlated with genetic distance. Murphy et al. (2010a) used this technique to demonstrate the importance of land cover, topography, and climate on western toad (*Anaxyrus boreas*) gene flow in Yellowstone National Park and Goldberg and Waits (2010) discovered that the importance of land cover type differed between two amphibian species (Columbia spotted frogs (*Rana luteiventris*) and long-toed salamanders (*Ambystoma macrodactylum*) inhabiting the same agricultural landscape. A buffer can also be applied to the straight-line network to incorporate a broader range of landscape variables among sites and test scale effects (Murphy et al. 2010a; Emaresi et al. 2011). This approach has the advantage of being a simple model with a limited number of assumptions. However, if dispersal movements leading to gene flow deviate strongly from a straight line, then this method will not be representative of actual gene flow. Pond-breeding amphibians such as toads may not violate this assumption because they can move over land between wetlands, but wetland species that are more closely tied to the aquatic environment are likely unsuitable for straight-line modeling.

A second common approach is to model connectivity among sites using least cost paths based on a resistance surface (Spear et al. 2010) (Figs. 2 and 3). A resistance surface represents the value of some variable thought to restrict gene flow, and least cost paths model the path of least resistance through this landscape. For instance, modeling gene flow as following a least cost path that maximized flow rate among ponds best explained genetic connectivity in the zooplankton *Daphnia ambigua* (Michels et al. 2001). Such least cost paths have the advantage of allowing researchers to model more realistic movement paths than straight lines, but are difficult to implement when the actual resistance of a variable is unknown. Furthermore, least cost path approaches assume a single path between populations, but if there are multiple suitable paths, the least cost path approach may not approximate landscape influence on gene flow well. A solution that has been proposed is to use electrical circuit theory to model how landscape features affect gene flow (McRae 2006). Circuit theory uses the same resistance surface as used for least cost paths but calculates resistances across all possible paths between sites. Therefore, this method takes into account redundant paths and likely is a more realistic approximation of gene flow. However, this method is not suitable for wetland-breeding species, as it

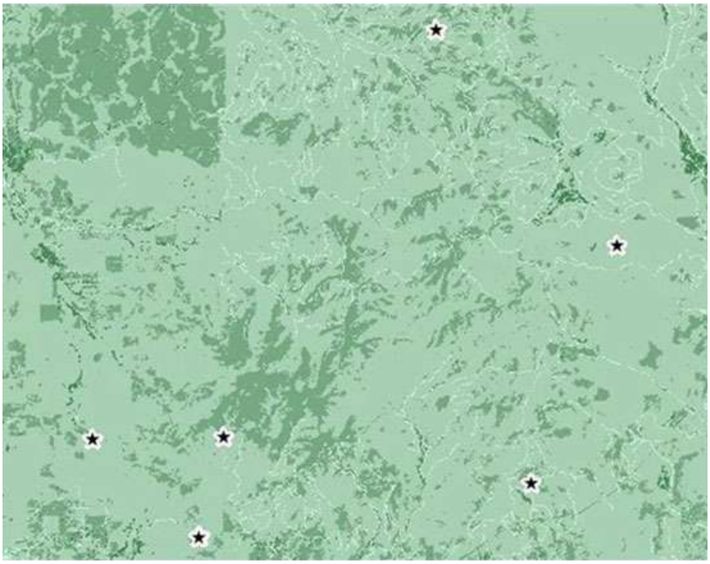

Fig. 2 Example resistance surface for a landscape genetic analysis. Stars represent genetic sampling sites. Background is a land cover map that has been coded to represent resistance. The darker color represents greater resistance to gene flow

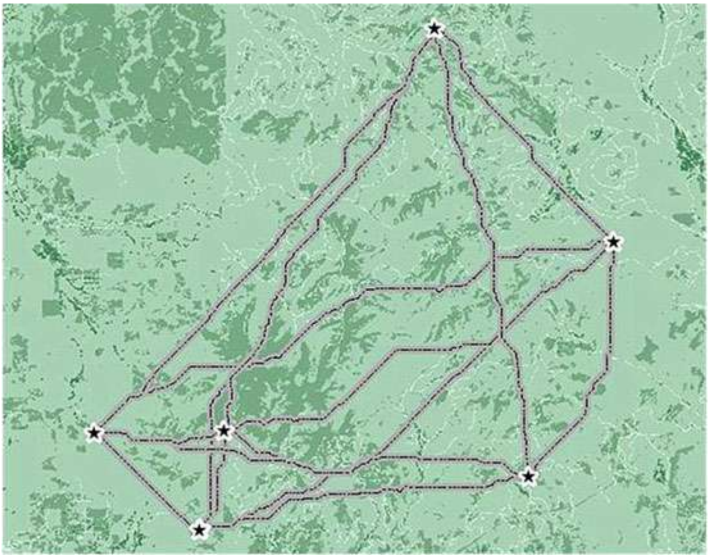

Fig. 3 Example of a least cost path connecting sites across the resistance surface in Fig. 2. Notice that dark areas are avoided by the least cost path

assumes that gene flow could take place at any location across the landscape. A new application of circuit theory for network patches has been developed, though not yet implemented in any empirical studies (McRae and Shah 2009). However, this network circuit theory may hold promise for wetland species due to the discrete nature of this habitat.

One disadvantage of either of the above approaches to landscape genetics in wetland systems is that both are measuring genetic connectivity as a function of the environment between wetlands and not at wetland sites. Therefore, this could limit insight into the characteristics of wetlands themselves that influence genetic connectivity. However, Murphy et al. (2010b) recently applied gravity models to landscape genetics. Gravity models allow researchers to model variables both at and between sites. Murphy et al. (2010b) used these models to demonstrate that wetland depth and heat load at wetlands were both important variables structuring a metapopulation of Columbia spotted frogs. Thus, this methodology may prove to be an important future direction in wetland landscape genetics.

Future Challenges

Landscape genetics is a relatively young and emerging field, and therefore, there are a number of future challenges and opportunities (Balkenhol et al. 2009a). The appropriate statistical analysis technique used to relate genetic and landscape data remains an important issue in landscape genetics. Landscape genetic studies typically use a regression framework, yet usually have pairwise genetic distances. This violates assumptions of nonindependence required for most regression analyses. This complicates both assessment of significance in regression models and typical model selection techniques such as the Akaike information criterion (AIC; Akaike 1974; Burnham and Anderson 2002). Permutation approaches using Mantel tests or multiple regression on distance matrices are one way to assess significance without violating assumptions, but some of these permutation techniques are controversial as to their efficacy (Balkenhol et al. 2009b). Furthermore, these permutation approaches do not address the problem of selection among alternative models. Some alternative methods have been recently proposed (Goldberg and Waits 2010; Van Strien et al. 2012), but have yet to be widely incorporated in empirical studies.

Another promising future application for landscape genetics is the incorporation of adaptive genetic markers in addition to neutral loci (Manel et al. 2010). This would allow researchers to distinguish between environmental factors that affect gene flow by affecting dispersal to those environmental factors that are leading to natural selection on organismal traits. The advances in sequencing large portions of genomic data have facilitated interest in adaptive landscape genetics, as it allows researchers to more easily identify regions of the genome under selection. For nonmodel species (such as most wetland species), there is still much work to be done to identify genetic markers of adaptive significance, but this avenue is especially interesting for predicting the effect of future climate change of species' ability to adapt and persist in novel environments.

Stephen F. Spear

Contents

Abstract

There are several concepts that are integral to an understanding of landscape genetics. These include concepts within the field of population genetics, including genetic drift, heterozygosity and neutral loci, which are described in this chapter. Additionally, I discuss issues related to statistical models used in landscape genetics. Overall, the definitions provided in this chapter should better allow a reader to understand terms in other chapters of this book in this volume.

Genetic Drift

Genetic drift is a process within the field of population genetics that describes how allele frequencies change due to random chance or sampling error (Hartl and Clark 2006). Genetic drift occurs most strongly in the absence of gene

(*continued*)

flow or natural selection and in small populations. The easiest analogy to consider for genetic drift is a coin flip. If two people flip a coin only a few times, it is unlikely that they will end up with exactly the same number of heads and tails. However, if the two people each flip a coin hundreds or thousands of times, it is much more likely that both will have a 1:1 ratio of heads to tails. Similarly, even if two populations are genetically identical initially, but only a few individuals reproduce, it is likely that they will begin to become different due to different alleles being passed on. Population genetic theory also demonstrates that genetic drift leads to loss of genetic diversity, with the rate of loss determined in large part by population size (Hartl and Clark 2006). This is why small populations are a concern from a genetic as well as demographic perspective, since loss of genetic diversity is associated with a reduced ability to adapt to environmental changes as well as inbreeding depression. In landscape genetics, a common assumption is that if populations are diverged genetically and the divergence is correlated with some landscape feature, then genetic drift is occurring due to reduced movement and consequent reduced gene flow between populations. Theoretical population genetic work demonstrates that as few as one successful migrant between populations is sufficient to stall the effects of genetic drift, so a landscape feature that is correlated with genetic divergence likely is quite strong as an isolating mechanism. Furthermore, if the landscape feature is indeed leading to genetic drift, it suggests that the population may already be small and of conservation concern, as isolation is much less likely to lead to detectable genetic change in large populations. Thus, landscape genetics can be a very effective conservation tool through its ability to detect environmental associations with genetic drift.

Definition

Heterozygosity

Heterozygosity describes the situation when a diploid individual has two different alleles present at the same gene or locus. The opposite of

(*continued*)

heterozygous is homozygous, in which an individual has two copies of the same allele at the same location. Heterozygosity, along with the number of alleles, is a primary metric used to assess the amount of genetic diversity in a population (Hartl and Clark 2006), and is usually presented as a population-level metric. In other words, heterozygosity represents the proportion of individuals within a population that has two different alleles at the same locus. It can be a useful metric of genetic diversity because the more alleles present in a population (and thus, the more diversity), the more likely that individuals will be heterozygous. From a functional perspective, high heterozygosity eliminates the effect of harmful alleles that are recessive. These harmful recessives will only be expressed in homozygous individuals, and the existence of these harmful recessives is one reason why high genetic diversity is considered important for conservation.

Definition

Neutral Loci

A neutral locus (plural: loci) is a gene that is not under natural selection, and therefore the specific form of that gene has no effect on individual fitness (Hartl and Clark 2006). Thus, neutral loci can only change due to random effects of genetic drift, gene flow, or mutation. Neutral loci are often regions of the genome that do not contain a sequence that codes for an amino acid, or they possibly could be a coding region in which there is no difference among all the alternative alleles with respect to individual fitness. An example of a type of genetic locus that is typically neutral and is commonly used in population genetics is a microsatellite; microsatellites are a sequence of many short repeats and thus are noncoding (Schlötterer 2000). Neutral loci are important in landscape genetics because we often wish to infer how the landscape or environment affects movement between populations, with the assumption that movement equates to gene flow. In contrast, a locus that was under natural selection could be similar in two isolated populations if the populations were under the same degree of natural selection. A drawback of using neutral loci to

(*continued*)

infer conservation status is that genetic diversity is not as important for neutral loci. Therefore, genetic studies that use neutral loci to infer conservation status are assuming that the diversity of neutral loci is representative of genetic diversity in general, which may not necessarily be the case (Reed and Frankham 2001).

Definition

Population Genetics

Population genetics is the study of how the frequencies of alleles (the various forms of a gene) change within and among populations (Hartl and Clark 2006). A population is typically defined as a group of individuals that are connected by random mating among them, and therefore tend to be genetically similar to one another, although in practice this can sometimes be difficult to assess. Population geneticists are interested in several evolutionary processes such as gene flow, genetic drift (see Genetic Drift), natural selection, and mutation. These processes can all change the genetic composition of populations, which has implications for evolution, ecology, and conservation. For instance, natural selection in different environments can lead to unique adaptations that may eventually lead to speciation. In contrast, the process of gene flow among populations tends to reduce the chance that populations will become different, but it may also provide beneficial genetic diversity that could prevent declines in small populations. In the context of landscape genetics, researchers are most interested in the relationship between genetic drift and gene flow (Storfer et al. 2007). For instance, if landscape or environmental features lead to increased similarity due to gene flow, we typically infer that these landscape features have facilitated gene flow among populations.

(*continued*)

Thus, we assume that individuals are able to physically move through these environments. On the other hand, if populations appear to be genetically different, then genetic drift due to population isolation is inferred, which suggests that individuals are unable to move across the landscape features. An emerging approach is to use landscape genetics to identify environmental features important for natural selection and adaptation. This type of investigation focuses on finding loci that have allele frequencies that are outliers when compared to an expectation of neutral genetic drift. The assumption is that the allele is selected for or against, and that is why it has a higher or lower frequency than expected by chance. These outlier loci are then correlated with landscape or climatic variables that might be agents of natural selection (Manel et al. 2010). These examples highlight how population genetics theory and assumptions form the backbone of more applied fields such as landscape genetics and conservation genetics.

Statistics for Landscape Genetics

One of the major considerations in conducting landscape genetic analyses is the appropriate statistical analysis. Many, but not all, landscape genetic studies are interested in correlating the levels of genetic differences or genetic diversity with landscape or environmental variables. The most common approach to such correlative approaches is multiple linear regression, but the problem with

(*continued*)

this approach is that genetic differences are expressed as pairwise distances in which the same population is used in multiple comparisons (Storfer et al. 2007). Clearly, in this situation, the genetic differences are not completely independent. Furthermore, there might be violations of independence simply due to the fact that populations that are close to each other in space are similar because they are neighbors, and as such cannot be considered completely independent. Thus, a major emphasis in landscape genetics is to identify statistical techniques that are not sensitive to violations of statistical independence. Some of the first possibilities were Mantel and partial Mantel tests. Mantel tests are regressions, but use a randomization approach to assess significance that was believed to deal with the nonindependence problem, and Mantel tests are currently the most widely used landscape genetic statistical analysis (Storfer et al. 2010). However, multiple studies have shown that Mantel tests often do not provide reliable results and may be biased (Raufaste and Rousset 2001, Balkenhol et al. 2009, Guillot and Rousset 2013, Graves et al. 2013). Other possibilities are models that include a regression coefficient that directly accounts for the nonindependence (such as a spatial term) (Spear and Storfer 2010), but such analyses have not been rigorously assessed in landscape genetics to this point. Analyses based on transportation flow, called gravity models, allow analysts to include both between-site landscape variables and landscape variables at the site to test their effects on genetic differences (Murphy et al. 2010). So far, gravity models seem to be reliable and provide the additional information of how habitat factors at a population influence genetic divergence. There are other methods that have been proposed as well, but in general, an appropriate statistical method is one of the grand challenges of landscape genetics.

water inputs and outputs are a function of hydrologic exchanges with atmospheric, surface, subsurface, and tidal systems. These exchanges are described using water budgets, hydropatterns, and residence times, which characterize the unique behavior of individual wetlands. Future challenges to wetland hydrologic functioning include natural and human alteration of wetlands and the surrounding landscape.

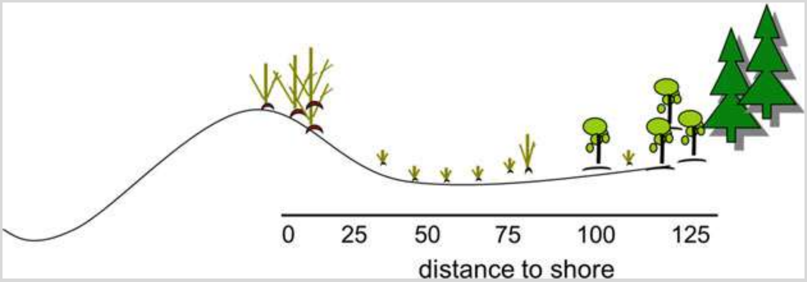
Definition: macrophyte
Author: Beth Middleton
A macrophyte is a type of vascular plant, which grows in wetlands, and includes emergent, floating, or submersed species.
Definition: zonation pattern
Author: Beth Middleton

(*continued*)



Zonation patterns of vegetation follow salinity and water depth patterns from shoreline to inland for the southeastern United States (e.g., salt marsh to freshwater bald cypress swamp)

Zonation patterns are apparent in vegetation, which form along environmental gradients. In wetlands, the underlying environment gradients are related to water depth, salinity, and other biogeochemical factors, and in the changes of dominant vegetation along the gradient.

Introduction

Wetlands are a unique landscape feature, which occupy the transition zone between permanently saturated aquatic environments (e.g., lakes, rivers, estuaries, oceans), and terrestrial environments with a root zone free of saturation during the growing season. Wetlands create unique biogeochemical conditions that differ from aquatic and terrestrial environments due to the low dissolved oxygen concentrations found in wetland soils. Anaerobic conditions are more likely to develop in saturated than in unsaturated soils due to the low oxygen solubility, slower rates of water advection, and oxygen diffusion in water compared to air.

Soil saturation thus serves as an indicator of the dissolved oxygen state of the soil-water system; wetter systems have higher water levels and lower soil dissolved oxygen concentrations, while drier systems have lower water levels and higher dissolved oxygen concentration. While anaerobic conditions promote many biogeochemical transformations, they also create adverse conditions for root survival and growth for many plant species. Because of these low oxygen concentrations, wetlands are among the most biologically productive ecosystems on the landscape, supporting diverse assemblages of species with special morphological and physiological adaptations, which enable them to survive and prosper in these otherwise harsh conditions.

Wetlands are generally found in low-energy environments, that is, on flat areas or on shallow slopes where water lies at or near the land surface, either above or below. Wetlands tend to form where surface water and groundwater accumulate within topographic depressions, such as along floodplains, within kettles, potholes, bogs, fens, lime sinks, pocosins, Carolina Bays, vernal pools, ciénegas, pantanos, tenajas, and playas, and behind dunes, levees, and glacial moraines. *Seepage* wetlands form where groundwater discharges on slopes, as well as near the shore of streams, lakes, and oceans. *Fringe* wetlands form along shorelines, with periodic inundation caused by water exchanges with adjacent waterbodies, such as floods and tidal action. *Perched* wetlands form in areas above low-permeability substrates where infiltration is restricted, such as clay, rock, or permafrost.

Because wetlands lie in low-energy environments, water velocities are slow and surface areas expand and contract as the water stage changes, promoting water storage. Wetlands therefore moderate hydrologic variability, storing flood flows and reducing flow velocities during wet weather, and releasing water slowly during dry weather. This water storage capacity is also related to the ability of wetlands to trap nutrients and sediments.

Wetland hydrology is integrally linked to other ecosystem processes (e.g., biology, soils, geochemistry) by complex processes with many potential feedbacks. For example, wetland microtopography can induce heterogeneous subsurface flows that create biogeochemical *hotspots*, which can vary over both space and time (Frei et al. 2012). Also, biogeochemical processes in wetlands linked to estuarine and marine systems demonstrate nonlinear relationships within nutrient cycles as a function of hydrologic behavior (Howarth et al. 2011). Understanding the coupled mechanics of wetland systems is important for understanding their influence on local, regional, and global ecosystem dynamics.

Hydrologic Descriptors

An important hydrologic descriptor of wetlands is the general elevation of water levels relative to the soil surface. Deep-water areas with few, if any, emergent macrophytes are known as *open water*. Vegetation present in these areas is usually not attached to the wetland bottom but may be floating on the water surface. However, tall woody species occasionally recruit during severe drawdown events, such as those caused by abnormally long drought, and may persist when water levels return to normal (e.g., *Taxodium distichum* and *Nyssa* spp. in southeastern swamps). Shallow areas containing substantial quantities of emergent macrophytic vegetation, either living or dead, are called *emergent zones*. Wetlands may also have large areas that are not flooded, but have a near-surface water table with macrophytic vegetation. Cowardin et al. (1979) proposes a general relationship between wetland water levels and hydric states.

Staff gages are used to monitor wetland water levels when the water level is above the ground surface (Fig. 1). The staff gage is a vertical scale that serves to indicate the elevation of water, or *stage*, with respect to a reference elevation. In some wetlands after a flood event, a water line can be observed on periodically submerged

Fig. 1 Staff gages are used to monitor the surface water level (stage). Multiple staff gages are used to monitor large stage variations, with gages more distant from the center of the wetland used during wet periods and gages in the deepest part of the wetland used during dry periods (Photo by the Illinois State Water Survey)

vegetation, or where floating debris (e.g., leaves, trash, branches) has been deposited on the shoreline or lodged in bushes and trees. In other cases, the normal water level can be observed as a horizontal stain on woody vegetation.

Piezometers are used to find the water level below the ground surface. A piezometer is a small-diameter perforated tube, which is installed within the soil to monitor groundwater levels over a specific interval of time. The perforated zone of the tube should be narrow to minimize the depth of soil monitored, and placed within a unique hydrogeologic unit, such as a soil horizon or geologic layer. Depth-to-water probes are commonly used to detect the belowground water level. For continuous measurements, automated dataloggers can be used with *pressure transducers*, *vibrating wire sensors*, or *capacitance sensors* to monitor above- and belowground water levels. Soil saturation can be measured using *time-domain reflectometry*, which determines the water content using the electromagnetic properties of a wave pulse passing through probes placed in the soil.

Hydropattern

The wetland *hydropattern* incorporates the timing, duration, and distribution of wetland inundation by quantifying the duration and frequency of water-level fluctuations. Spatial and temporal changes in water levels are important determinants of habitat suitability for many aquatic flora and fauna. The reproductive success of these wetland species can be adversely affected when fluctuations are not correctly synchronized with their developmental stages. The hydropattern of some systems, such as tidal marshes, fluctuates dramatically over short periods of time; other systems, such as seasonally flooded bottomland hardwood swamps, fluctuate more slowly over time. Other wetland systems are more static and may not display substantial short- or long-term variability. The wetland hydropattern is a function of the landscape topography and the net difference between inflows and outflows from atmospheric, surface, subsurface, and marine sources.

The *hydrograph* relates the wetland stage as a function of time (Fig. 2a). Ideally, the hydrograph should have sufficient duration and frequency so that it captures the range of possible hydrologic variability. Interannual, seasonal, event, and daily water-level fluctuations in a wetland should then be apparent. Water levels typically rise in response to precipitation, and then decline slowly over time. The *time to peak* is the time between the peak precipitation and peak stage. Times to peak are short in urban areas with high amounts of impervious surfaces and channels that have been modified to increase stream velocities. Times to peak are longer in forested areas with few impervious surfaces and high channel complexity.

The *stage-duration* relationship provides a descriptive summary that indicates how long a typical flood lasts for each stage (Fig. 2b). Lower stages typically show longer durations than higher stages. This approach is useful for characterizing water level variability using the duration that a specified water level is exceeded and can also be used to determine the seasonal nature of inundations by segregating the data into specific time frames. While the stage-duration approach successfully captures the duration of time that the system is flooded, it does not indicate the frequency of flooding.

The *stage-frequency* relationship is an alternative approach that quantifies the frequency in time that the wetland is observed to exceed a range of specified stages (Fig. 2c). This approach provides a cumulative frequency plot (or table) that can be used to calculate exceedance probabilities. The mean, median, and extreme stages (e.g., 1, 10, 50, 90, and 99 percentile probability) can be estimated using the stage-frequency relationship.

The two previous relationships can be combined to yield the *stage-duration-frequency* relationship, which is used to determine the hydrologic behavior for a range of probabilities and durations. That is, a system whose water levels vary slowly over time displays a different duration and frequency than rapidly fluctuating systems. Partitioning or stratifying data sets into seasonal or other periods may improve the characterization of water level conditions (Mitsch and Gosselink 2007).

Water Budgets

A water budget accounts for the gains and losses of water storage in a wetland system. When hydrologic inputs exceed outputs, the surplus water increases the water storage within the wetland, causing water levels to rise. For example, if rainfall inputs exceed evaporation, seepage, and discharge outputs, then the total effect is to

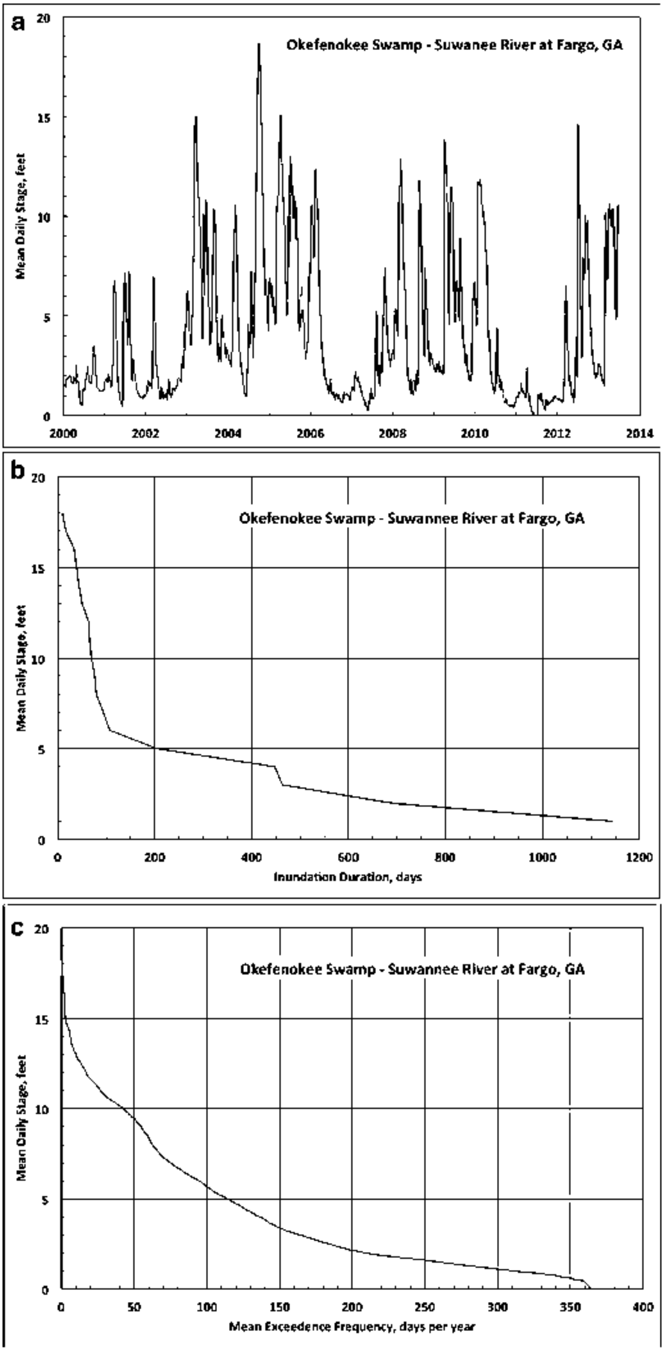


Fig. 2 Hydropattern example for Okefenokee Swamp showing (**a**) hydrograph, (**b**) stage-duration relationship, and (**c**) stage-frequency relationship

raise water levels within the wetland. Hydrologic inputs and outputs are expressed in units of volume, $\mathbf{V}$, or depth, $\mathbf{D} = \mathbf{V/A}$, (where $\mathbf{A}$ is the wetland area) per unit time, $\mathbf{\Delta V/\Delta t}$ and $\mathbf{\Delta D/\Delta t}$, respectively. These water level and volume changes result from accumulated inputs and outputs over space and time. Wetlands attenuate downstream water-level fluctuations by storing water during wet periods and releasing them during dry periods.

Subsurface water storage depends on the specific yield (i.e., the drainable porosity) of the organic and mineral sediments in the underlying soil. The specific yield, $\mathbf{S_y} = \mathbf{(\Delta V/\Delta D)/\Delta A}$, is the volume of water released, $\mathbf{\Delta V}$, per unit decline in water level, $\mathbf{\Delta D}$, per unit area, $\mathbf{\Delta A}$. In many cases, organic and mineral sediments may remain at or near saturation as water levels fall. In these cases, only a small volume of water is released from the sediments during drainage. Specific yields of sediments are strongly influenced by their particle size distribution and chemical composition; sands have larger specific yields, while clays and organic soils have lower specific yields.

Residence Time

The hydrologic residence time within a wetland provides a metric that can be used to indicate the rate of water exchange (or turnover rate) within the system. Some wetlands exchange water quickly, having a short duration of time that water remains within the wetland, while water may travel very slowly through other wetland systems.

The mean residence time, $\boldsymbol{\tau} = \mathbf{V/Q}$, is the ratio of the volume of water within the wetland, $\mathbf{V}$, to the average flow through the wetland, $\mathbf{Q}$. Short residence times occur when the flow through the wetland is large compared to its volume, and longer residence times occur when the flow is small compared to its volume. The residence time of a wetland is often related to its hydropattern; wetlands with large water-level fluctuations may have shorter residence times, such as in tidal marshes. On the other hand, some wetlands may fluctuate rapidly due to large changes in inflow; yet have very long residence times due to slow loss rates.

Different parts of a wetland may exhibit different residence times; water in an active, flow-through portion of a wetland may have shorter residence times than water in an inactive, isolated portion of a wetland. While each section of a wetland may have identical hydropatterns, the flow is concentrated in one area, leaving other areas with stagnant conditions. The same equation can be applied regardless of the situation; each section would be characterized using the volume and flow rate in the section of interest. Residence times for dynamic systems are more complex than steady flow systems. In these cases, the residence time is not a constant, with longer residence times during periods when outflows exceed inflows, and shorter residence times inflows exceed outflows. This situation results as a consequence of the fact that residence time is influenced by the rate of adding new water as well as removing old water from the wetland.

Hydrologic Exchanges

Wetland hydropatterns, water budgets, and residence times are influenced and controlled by water exchanges (inflows and outflows) with the surrounding environment. The four general types of wetland water exchanges include atmospheric, surface, subsurface, and tidal, and are discussed in the following sections. Brinson (1993) characterized wetlands based on the type of hydrologic inflow, noting that wetlands have different types of inflow and outflow patterns. That is, some wetlands have simple exchanges with adjacent waterbodies, such as when a wetland receives water from a flooding river during the rising stage and returns water to the river during the falling stage.

Another type of wetland hydropattern is due to tidal exchange along the coast, where water moves in and out of wetlands to its original source. In other cases, exchanges may be between different types of waterbodies and have a hybrid character, so that inflows may be of one type (e.g., subsurface inputs) and outflows may be of another (e.g., evapotranspiration). Identifying and characterizing the wetland hydrologic exchanges is critical for understanding hydrology and ultimately in managing wetland systems.

Atmospheric Exchanges

Atmospheric exchanges include *precipitation inputs* (e.g., rain, snow, hail, sleet, freezing rain, fog drip, dew, frost) and *evapotranspiration* (e.g., evaporation, transpiration, interception). Water levels in wetlands that are dependent on atmospheric exchanges tend to be more affected by climatic signals than those dependent on groundwater sources (Orme 1990). Precipitation generally occurs as discrete events, characterized by the intensity, duration, frequency, and areal extent. In aggregate, these precipitation events can be described using monthly and seasonal averages, along with longer-term variability associated with decadal and climatic fluctuations.

The loss of water from a wetland by evapotranspiration (process by which water is lost from the water surface as well as from plant leaf and stem surfaces) can have large effects on water levels. Evaporation dominates when open water is present. Saturated soils may lose nearly as much as open water, but not if a litter or mulch layer is present. Transpiration dominates in systems with little open water and large coverage of living vegetation. Evapotranspiration rates are affected by leaf and stem area, air, water, and plant temperatures, atmospheric humidity, wind speed, and the water potential of exposed soils.

Precipitation and evaporation can be readily measured using raingages and evaporation pans, respectively. These tools are relatively inexpensive and provide reliable estimates of daily atmospheric exchanges. A single raingage is usually sufficient for small wetlands (e.g., smaller than 100 ha), but multiple raingages may be required for larger wetlands, especially if significant spatial variation in rainfall is present. Pan evaporation rates can be used to estimate evapotranspiration rates, with a single pan usually being sufficient for all but the largest wetlands.

However, local effects of shading and wind shelter can adversely affect the accuracy of the measurements.

Surface Exchanges

Surface water exchanges result from a large number of mechanisms, including overland (or sheet) flow, direct exchange when the channel of a river or stream flows through the wetland, overbank flooding during wet weather when the channel is separated from the wetland by a levee or floodplain, and along the edges of lakes, estuaries, and the ocean. These surface exchanges result in either constant or episodic hydrologic communication between the surface water and the wetland. Streamflow can be divided into two types, *baseflow* and *stormflow*. Baseflow is that component of flow found during low flow periods, while stormflow refers to the response to precipitation events. If a stream was flowing before the rainfall (a typical situation), stormflow is the flow attributable to the rainfall and occurs in addition to the baseflow.

Surface water flows can be estimated using flow measurement control devices, such as *weirs* (which require a pool upstream and are not satisfactory when elevated sediment concentrations are present), *flumes* (which tend to flush sediments more effectively than weirs), and *culverts* (which are less accurate for surface water flow measurement). The relationship between stage and streamflow discharge is called the *rating curve*. The stream discharge is readily found using the observed stage and the rating curve.

Subsurface Exchanges

Subsurface inflows to wetlands result from shallow, topographically induced drainage from nearby uplands, or from discharges of regional, confined aquifers. Subsurface outflows from wetlands result from downward (or lateral) flow from the wetland to underlying surficial aquifer or to deeper, confined aquifers. Shallow inflows may result from perched drainage (also called interflow) on top of lower-permeability units such as clay beds, soil horizons, or even permafrost. Shallow subsurface inflows may also arise when the water surface within the wetland lies below the water table in the underlying surficial (unconfined) aquifer.

Subsurface inflows from deeper sources may arise when confined aquifers discharge into the wetland, either at discrete points (such as springs) or as diffuse upward leakage through the underlying surficial aquifer. Shallow inflows may respond more rapidly to individual storm events, as well as to seasonal and climatic changes. This rapid response is because interflow and water levels in shallow aquifers tend to be more sensitive to net changes in atmospheric flux (precipitation less evapotranspiration) in nearby upland areas.

Shallow subsurface outflows may occur if a layer of low permeability underlies the wetlands and causes the water to perch. In these cases, a low point on the perimeter of the wetland allows water to exit the wetland as overland flow, channel flow, or interflow. When wetland water levels are contiguous with water levels within the surficial aquifer, flow through the surficial aquifer may be affected by the wetland.

Normally, surficial aquifer water levels dip in the direction of water flow, while the general water level elevation in the subsurface layers of the wetland are more uniform (Fig. 3a). Thus, wetland water levels are lower in the upgradient direction and higher in the downgradient direction. As a result, aquifer discharge conditions are present at the upstream end of the wetland, and recharge occurs at the downstream. This type of flow-through wetland may account for most of the flux of water through a wetland that has no readily apparent inflows or outflows. Finally, recharge to deeper, confined aquifers may occur when subsidence or collapse has breached the confining layer that isolates the aquifer from the surface. In this case, water level increases in the wetland during wet-weather periods may cause direct recharge to the deeper aquifer (Mitsch and Gosselink 2007).

Groundwater flow normally varies over both space and time, so that multiple vertical and horizontal measurements at a sufficiently frequent time interval may be needed to characterize the system. Spatial variability can be determined by placing an array of piezometers near the wetland (Fig. 3b). Multiple piezometers (called a *nest*) can be placed at different depths at each location to evaluate the magnitude of vertical flow (Fig. 3c).

Water quality sampling can be used as an independent method to determine the source of water within wetlands. For example, if shallow groundwater is moving laterally into the wetland, and groundwater is also moving upward into the wetland from a deeper aquifer, then the geochemical signature of each source can be used to evaluate the relative magnitude of each inflow relative to the total.

Tidal Exchanges

Coastal wetlands are similar in many ways to freshwater wetlands, except that they are transitional between marine, freshwater, and terrestrial environments. Coastal wetlands occupy similar landscape positions as lacustrine wetlands, except that water quality can have greater variation due to mixing of marine and freshwater. Besides water-quality variation, water levels in *tidal* wetlands vary with the regular ebb and flow of ocean water levels, which can affect wetlands many miles inland. The hydrodynamic conditions imposed by tidal fluctuations can cause rivers to slow, or even reverse flow direction, many miles from the coast. The magnitude of this effect usually diminishes with distance upstream, and is a function of local channel features. The combination of water level and water quality changes promotes ecologic diversity and productivity in these wetlands.

Many coastal wetlands are affected by nearby freshwater inputs, especially in estuarine environments. In these cases, occasional, large stormwater inflows can cause rapid changes in the salinity, temperature, dissolved oxygen, and sediment

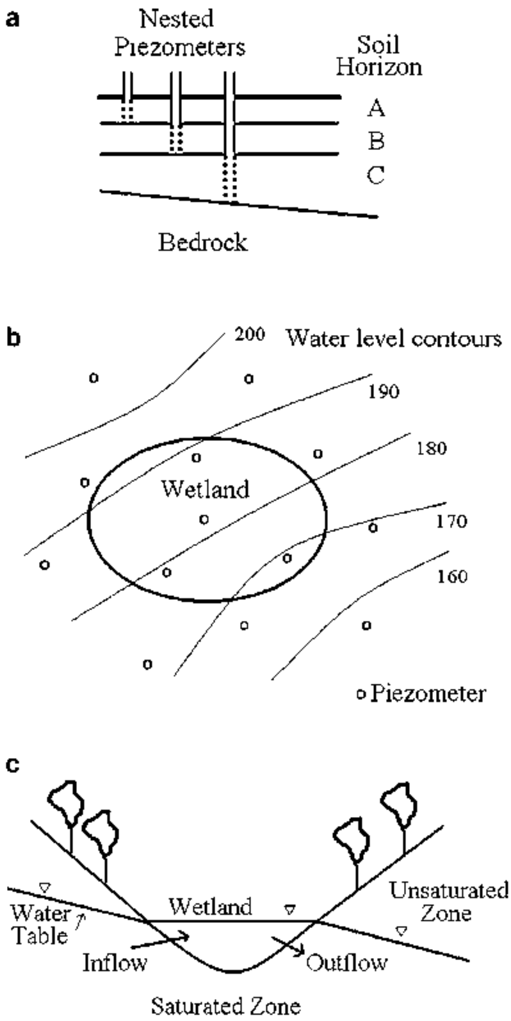

Fig. 3 Piezometers are used to monitor subsurface water levels: (**a**) Multiple piezometers (called a *nest*) can be installed at different depths if vertical flow is suspected; (**b**) Network of piezometers are used to map water levels near a wetland and contours determined by interpolation between piezometers; and (**c**) Subsurface water movement in the vicinity of the wetland inferred from piezometer data

concentration within the wetland. These inputs can be beneficial in some cases, such as historical sediment deposition in the Mississippi River Delta of southern Louisiana, in contrast to the current practice of diverting stormflows away from coastal wetlands, which has led to regional subsidence and saltwater intrusion. In other cases, these inputs can be detrimental, as when increased urban wastewater and stormwater inputs to coastal estuaries alter natural conditions.

Differentiating marine from freshwater (both surface and subsurface) inputs can be achieved using geochemical information. Marine water has high concentrations of sodium chloride type water, while freshwater inputs normally have markedly lower specific conductivities and total dissolved solids. Depending upon location, subsurface inputs are intermediate, with possibly distinct geochemical signatures. For example, a calcium signal may be present in regions with carbonate aquifers. The degree of tidal flushing can thus be monitored using water quality data to characterize the residence times of water within the system. Fluxes can then be estimated using a water budget approach.

Future Challenges

Wetlands change over time due to both natural processes (e.g., beaver activity, natural erosion, and eutrophication) and those caused by humans (e.g., upstream development, wetland removal, cultural erosion, and eutrophication). Some of the many factors that cause wetland hydrologic functions to change over time are discussed here, especially those that compromise the important ecosystem services those wetlands provide.

Natural Change in Wetlands

Wetlands result from many natural processes. Rivers create floodplains, which provide a landscape position that promotes wetland development. Glaciers scour the landscape, leaving behind features that also promote wetlands. Tectonic uplift and subsidence create depressional features that are favorable to wetland formation. Carbonate aquifers dissolve over time, leaving behind depressions where wetlands can form. Erosion transports sediment out of natural channels, leading to downcutting and deepening of channels, which leads to a lowering of riparian water tables and the reduction of overland flows, both of which alter wetland saturation.

Wetlands can also modify their environment as they mature; peats may substantially modify the original landscape by filling in the depression that originally created them. Other biological forces also promote wetland formation. Some examples include beaver activity, which creates impoundments that form natural wetlands in habitats that are favorable to their needs, and large woody debris dams that impound shallow wetlands. Wetlands age over time, slowly filling in with external sources of materials, such as sediments from upland erosion, as well as with detrital materials from wetland vegetation. Rates of deposition of these materials can be slow, such as in oligotrophic systems with small upstream catchment areas. Alternatively changes can be rapid, such as in nutrient-rich areas with large upstream locations prone to extensive natural erosion.

Wetlands in a natural setting are constantly being formed and lost, so that wetland hydrology also changes over time. Reducing wetland water storage decreases the residence time and alters the hydropattern. The dynamic nature of hydrology (especially when applied to wetlands) means that wetlands cannot be investigated apart from their regional environment.

Human Alteration

Humans have substantially increased hydrologic disturbances within watersheds (Azous and Horner 2001). These changes generally cause increased sediment production and transport, as well as increases in nutrient concentrations and loads. Such increases cause reductions in wetland water storage due to sediment trapping and nutrient uptake with subsequent deposition of organic sediments.

Routing stormwater runoff from urban, industrial, and agricultural areas can increase surface inflows to wetlands. Inflows are also altered when hydraulic structures, such as reservoirs, canals, levees, dikes, revetments, and jetties obstruct or alter natural hydrologic patterns. Many of these alterations resulted from efforts to drain wetlands. Outflows from wetlands were increased by the construction of drainage ditches, channels, and canals, or the removal of natural barriers, such as vegetation, and by straightening streams.

Other efforts to drain wetlands used groundwater extraction techniques, such as underground tile drains and pumping wells that lower groundwater levels. Lowering of water tables can affect wetlands by increasing subsurface drainage from the wetland to the point of groundwater extraction. Ditches and tile drains increase the discharge of shallow groundwater, thus lowering water tables in their vicinity. Tile drains promote shallow groundwater flow, thus favoring drier conditions within the wetland.

Drainage of agricultural fields may reduce surface water inflows, lower water tables, and reduce the seasonal period of soil saturation. Groundwater pumping in the vicinity of the wetland can lead to a reduction in shallow aquifer water levels, while irrigation may increase water levels, resulting in either decreases or increases in wetland water levels, respectively. The effects of regional groundwater pumping tend to manifest themselves as slow (and in some cases, rapid) declines in regional, confined aquifer levels. These declines in regional water availability are then transmitted to changes in wetland hydrology by reductions in diffuse upward leakage or direct connections to wetlands, resulting in the lowering of water levels in wetlands.

While beaver-created wetlands once dotted the landscape, trapping and eradication efforts have substantially reduced the populations of these animals. Also, the clearing of large woody debris from rivers may also reduce wetland formation. Harvesting of riparian vegetation, particularly the larger diameter trees could result in poorer recruitment of large woody debris. While wetlands clearly affect vegetation, fish, and wildlife, it is also true that these biological factors affect wetlands.

The construction of surface-water obstructions (e.g., levees, road and bridge embankments) may deprive the wetland of natural flows. In some cases, obstructions may not substantially alter total wetland outflows. Obstructions may just alter the stage-discharge relationship, requiring a higher water level in order to pass an equivalent discharge. This change in discharge rate may have both positive and negative effects on wetlands. Increased water levels can alter the natural storage ability (an adverse effect for flood mitigation), but may increase the residence time (a positive effect for water quality enhancement).

Alteration of the coastal morphology by altering the landscape (e.g., channel dredging and canal construction) can adversely affect natural wetlands by increasing saltwater intrusion rates. Density-dependent stratification of estuarine waters may alter saltwater mixing in coastal areas. Construction of deepwater navigation channels may allow saltwater to migrate inland, resulting in increased salinities.

Coastal groundwater pumping affects coastal wetlands by reducing artesian pressures in underlying confined aquifers, which may then cause a reduction in discrete and diffuse upward leakage. Groundwater pumping may also cause coastal subsidence, resulting in the effective lowering of the ground surface relative to the sea level, causing the intrusion of saline water into coastal wetlands. Pumping from shallow aquifers can also lower coastal zone water levels, causing local dewatering of coastal wetlands. Shallow disposal of septic wastes can alter local groundwater quality by increasing organic and nutrient loading and decreasing dissolved oxygen concentrations, which may subsequently affect local wetlands.

Restoration

Efforts toward restoration of the hydrologic function of compromised wetlands are expanding (Means and Hinchee 1999). Efforts are also being undertaken to create artificial wetlands that take advantage of natural functions that wetlands provide (Kadlec and Wallace 2001). For example, efforts to mitigate stormwater runoff include designing and constructing artificial wetlands that mimic the beneficial hydrologic effects of natural wetlands. These efforts seek to achieve specific management goals that require reductions in nutrients, sediments, and peak flows. It is also apparent that increased stormwater loads, along with decreased retention times, substantially decreases the effectiveness of wetlands in storing water during flood periods and subsequently releasing them during dry periods. The resulting hydrologic performance of affected wetlands may be compromised.

Regardless of whether impaired wetlands are being restored, or new wetlands are being created, the intent is to recreate the hydrologic behavior that maximizes ecosystem services. The emphasis in these cases is the design and evaluation of alternative strategies for wetland restoration. Manipulating the stage-discharge relationship can control water levels in wetlands. Changing the elevation of an outflow structure (e.g., raising the base of an outlet weir elevation) changes the wetland water levels and flooded areas. The base elevation along with the rate of change in discharge with elevation can be adjusted using outflow structures of different sizes and shapes, depending upon the desired outflow characteristics. Other hydrologic alteration possibilities include closing of ditches and drains, thus reducing wetland outflows. Removing artificial obstructions, such as roads and berms can also improve flow through the wetland by recreating natural hydrologic communication with neighboring waterbodies.

These principles apply not just to freshwater wetlands but also apply to the restoration of tidal wetlands, which requires the recreation or simulation of natural hydraulic conditions (Zedler 2001). Weirs and ditch plugs are devices used in tidal marshlands to maintain minimum water levels. Weirs are useful because the bottom elevation of the weir controls the minimum elevation on the upstream side, but allows higher flows to pass unaffected. Ditch plugs provide the same control, but are more susceptible to destruction during high flows.

largely influenced by the tides and factors that affect the tides such as the position of the moon and sun relative to the Earth's surface, local weather conditions, and river discharge. Consequently, site wetness is dynamic, changing daily. For example, some portions of coastal wetlands are inundated nearly every day by the tides, while other portions are infrequently flooded.

Introduction

Hydrology – the frequency, duration, and timing of inundation and/or soil saturation – is the lifeblood of wetlands. Hydrology strongly influences the physical and chemical environment, biota, productivity, and connectivity of habitats within wetland complexes and between wetlands and waterbodies. Therefore, hydrology has a powerful influence on the usage of wetlands by humankind and other animals. Wetland hydrology (e.g., prolonged flooding and/or saturation) typically creates anaerobic soil conditions that have a great effect on plant and animal life. The degree of wetness separates wetlands from terrestrial habitats, produces biological diversity among wetlands, and provides wetlands with unique properties and accompanying functions, which make them highly valued natural resources. Wetlands typically form wherever there is a seasonal excess of water for a few weeks in most years during the time when temperatures are warm enough to initiate and support plant growth.

Wetlands occurring along the shorelines of the world's oceans, estuaries, and tidal rivers are called coastal wetlands or tidal wetlands. Their hydrology is largely influenced by the tides and factors that affect the tides such as the position of the moon and sun relative to the earth surface, local weather conditions, and river discharge. While tidal beaches and rocky shores along the world's oceanic shoreline have been included as tidal wetlands, the majority of the world's tidal wetlands are marshes, tidal flats, and mangrove swamps. These types have formed in places where ocean currents and wave action have been reduced allowing sediments to accumulate, creating intertidal environments. Coastal wetlands are typically found behind protective features such as spits or barrier islands, in sheltered (semi-enclosed) embayments, or along coastal rivers. While wetlands along large freshwater lakes, most notably North America's Great Lakes, have been described as coastal wetlands, the effect of tides on these coastal wetlands is minimal so that these are not considered tidal wetlands. The focus of this summary will be on the hydrology of tidal wetlands in North America. The discussion will not address the effects of hydrology on water quality or biota. Much of the text has been adapted from *Tidal Wetlands Primer: An Introduction to their Ecology, Natural History, Status, and Conservation* (Tiner 2013).

Water Budget

The degree of wetness in a wetland at any point in time is a net result of water inputs versus outputs. Inflows increase site wetness with water coming from four sources: (1) precipitation (P) – rain, snow, sleet, hail, or fog, (2) surface water inflow (Si) – rivers, streams, and surface water runoff from the land, (3) groundwater inflow (Gi) – water discharged to the wetland surface (seepage), and (4) flood tides (Ti). Outflows reflect water losses from: (1) evapotranspiration (ET) – the combination of evaporation and plant uptake of water and loss through transpiration, (2) surface water outflow (So) – water draining to rivers or streams, (3) groundwater outflow (Go) – water recharging underground aquifers, and (4) ebb tides (To), which are falling tides that drain water off the surface and lower water tables. The water budget is expressed by a simple formula that compares inflows versus outflows and yields a net change in volume (ΔV):

$$\Delta V = [P + Si + Gi + Ti] - [ET + So + Go + To]$$

When the inputs exceed the outputs, the wetland stores water either in its soil or both in the soil and on its surface (inundation). When the opposite occurs, there is a net loss of water from the wetland and there is no surface water and the water table drops below the surface. The water table and presence of surface water are dynamic characteristics of wetlands. The main difference between the water budget equations for a tidal versus a nontidal wetland is thus the tidal input and output variables. While the tides are just one factor affecting site wetness, tides are the dominant factor in wetness for most tidal wetlands, especially those subject to frequent tidal flooding. Along the upland border, however, groundwater discharge and surface water runoff may play significant roles in site wetness as illustrated by the presence of seepage areas with distinctly different vegetation (i.e., species with more freshwater affinities) than found in the contiguous salt marsh. For freshwater tidal river swamps, surface water inflow during spring freshets is a major factor contributing to the annual water budget, especially for those infrequently flooded by tides. High evapotranspiration coupled with infrequent tidal inundation has an enormous effect on site wetness in semiarid and arid regions or areas with Mediterranean climates. Given the significance of the tides as a driver of coastal wetland hydrology, an introduction to the tides is critical for understanding the hydrology of coastal wetlands.

The Nature and Variability of Tides

Observed tides are the result of the gravitational forces of the moon and the sun exerted upon the water on the Earth as modified locally by weather conditions (e.g., wind and precipitation). According to Newton's law of gravity, the force of attraction between two bodies is proportional to the product of their masses and inversely proportional to the square of the distance between their centers. So even though the moon is only 1/400th the size of the sun, the moon has a stronger influence on the tides because it is closer to the Earth. The moon's influence on the Earth is about 2.25 times greater than the sun's (U.S. Army Corps of Engineers 1991). Given orbits of the moon around the Earth and the Earth around the sun, the interaction of lunar and solar effects on the tides varies daily, seasonally, and annually. The moon's orbit is elliptical, so once a month the moon is closest to the Earth (at perigee) and the tides will be higher than usual. Two weeks later it will be furthest away (at apogee) and tides will be lower. The Earth's orbit around the sun is also elliptical so that the Earth is closest to the sun around January 2 (perihelion) and furthest away around July 2 (aphelion) with corresponding effects on the tides. When the perigee and perihelion coincide, the highest tides occur.

Types of Tides

A tidal cycle consists of one high tide and one low tide. While recognizing that no two tide cycles are exactly alike, tides have been classified into three types: diurnal, semidiurnal, and mixed (Fig. 1). *Semidiurnal tides* occur when two tidal cycles take place each day, with high or low tides of more or less equal height. *Mixed tides* are characterized by two daily tides of distinctly unequal height: typically, a "higher high

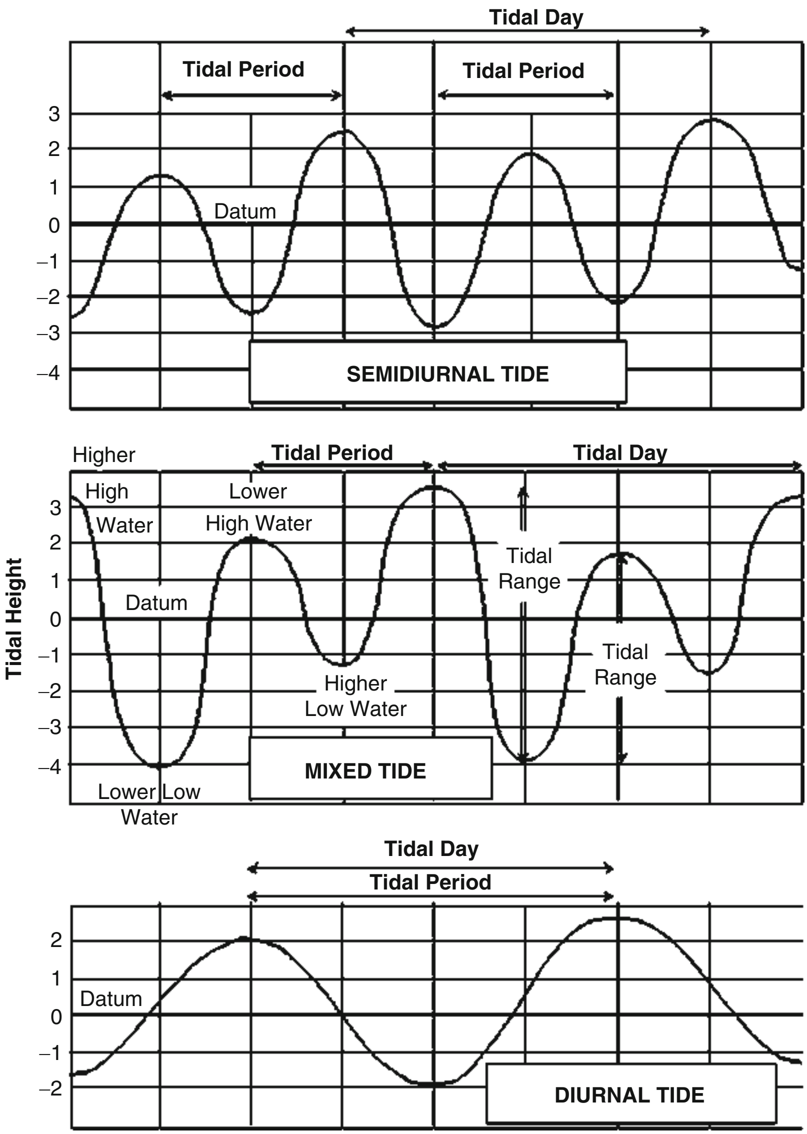

Fig. 1 Three main types of tides that occur over a lunar day– 24-h and 50 min, which is the time it takes for the moon to circle the Earth (Zevenbergen et al. 2004; US government publicaton)

tide" and "lower high tide" and a "higher low tide" and "lower low tide." Where only one tidal cycle occurs during a twenty-four-hour period, the tides are called *diurnal*.

Depending on the position of the moon relative to the sun, other tides occur at 2-week intervals. On new and full moons when the sun and moon are aligned in a straight line ("syzngy"), the highest astronomic tides – "spring tides" – are produced

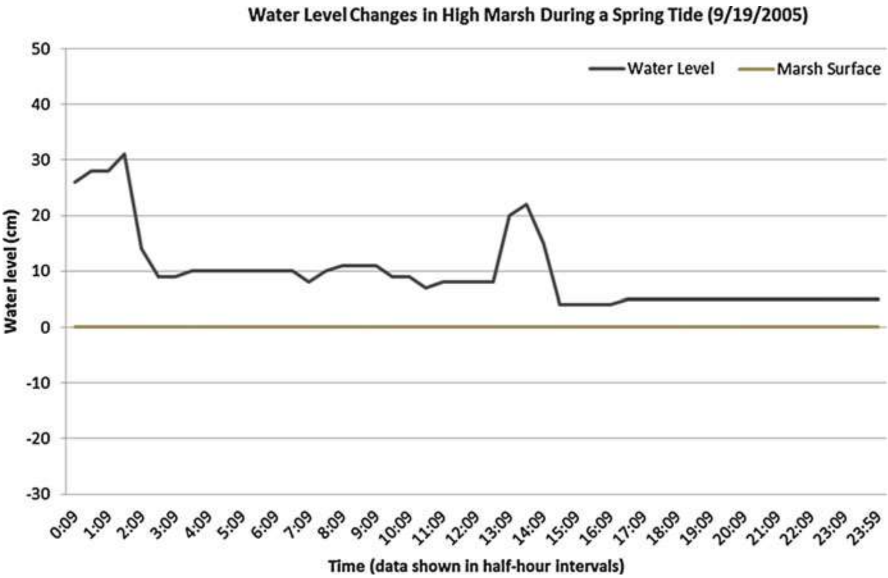

Fig. 2 Most if not all of the high marsh is flooded by spring tides. This site was flooded continuously during a tidal day (2 high and 2 low tides) (Source: Robert Vincent, used with permission). The marsh surface is at 0 cm (Source: Robert Vincent, used with permission)

by the combined gravitational pull of the moon and sun. These tides will flood the uppermost portions of salt marshes at high tide (Fig. 2) and expose the lowest levels of the intertidal zone (e.g., tidal flats) at low tide, resulting in the highest tidal range. About a week after the spring tides, the sun and moon are 90° apart in relation to the Earth (i.e., moon's first and third quarters) so their gravitational forces work against each other, minimizing the pull on the Earth's oceans. These conditions create moderated tides called "neap tides" and produce the lowest tidal range. These tides often do not flood the higher elevations of marshes, but they produce fluctuations in the water table of the high marsh (Fig. 3). The highest spring tides occur during full moons and the lowest neap tides happen during the first quarter after the new moon (R. Vincent, pers. comm. 2013). Neap tides can be at a relatively high level (relative to mean sea level) during third quarter after the full moon and inundate portions of the high marsh despite having a low tide range.

While the lunar cycle of the spring and neap tides repeats itself roughly every 30 days, it takes the moon 18.6 years to repeat its four phases at the same day of the solar year. At some point during this cycle (metonic cycle), the highest and lowest astronomic tides occur. The number of extreme high tides appears related to the declination of the moon (angle of the moon relative to the equator) over the 18.6-year period; about every 9.3 years the number of extreme high tides increases around the time of high-maximum lunar declination, whereas 9.3 years later or earlier, the lowest number of extreme high tides occur during the low-maximum phase (Wood 2001).

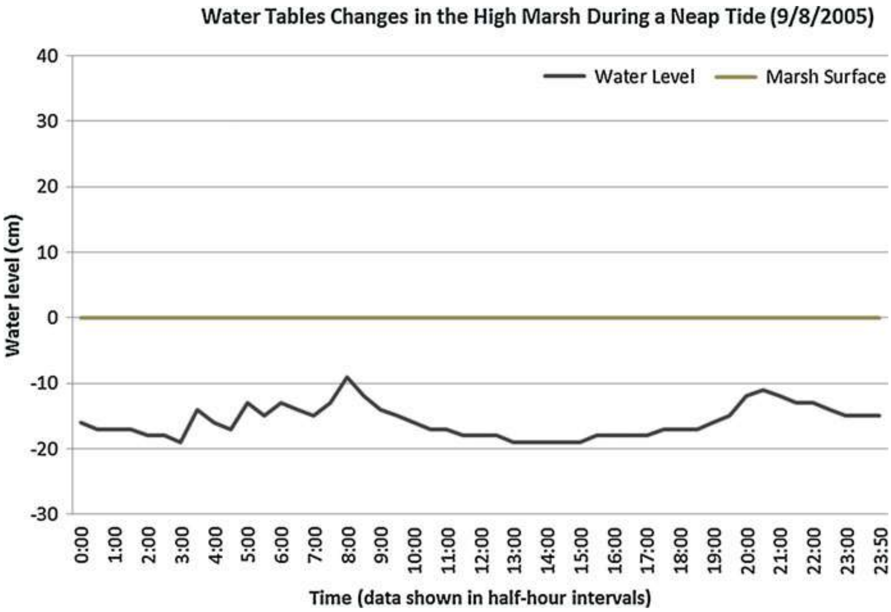

Fig. 3 Tidal signal in water table of high marsh during neap tides (Source: Robert Vincent, used with permission) The marsh surface is at 0 cm

Other Factors Affecting Tides and Coastal Wetland Water Levels

While charts of predicted tides show a repeating cycle of high and low tides, the amplitude of tides and the height of the tide at any given time and the duration of flooding of coastal wetlands are affected by other factors including the morphology of the estuary, river discharge, local weather conditions, and tsunamis (high waves created by earthquakes on the sea floor). The tidal effect in the marshes and swamps is further complicated by elevation, soil properties, and other factors, so the further one gets from the waterbody, the more other factors may influence site wetness in a tidal wetland.

Geomorphology

The behavior of the tides in an estuary is largely governed by the size and shape of the estuary and offshore bottom characteristics. As a result, some estuaries have higher tides further away from the sea, while others do not. Some estuaries have diurnal tides, while others nearby have semidiurnal tides.

The Bay of Fundy has a rare geomorphology that creates extraordinary tides that are among the highest tides in the world, reaching heights of >16 m (Parkes et al. 1999). The basin's funnel shape and gradual decrease in depth cause a great rise in tides from a 6 m tide at its mouth to a 16 m tide at its upper end. These huge tides are also the result of a so-called “bathtub effect” where water sloshes back and forth within this marine basin. This sloshing effect is nearly in sync with the lunar tides so these forces act in harmony to produce tides of enormous proportions. Storm tides can generate tides of 21 m or more. Peak tides occur at three cycles: 7 months, 4.53 years, and 18.03 years, with the latter generating the highest tides (Desplanque and Mossman 1998).

Local Weather and Climate

Local climatic conditions, especially winds and storms (e.g., hurricanes), influence the actual height, duration, and frequency of tidal flooding. Actual tides therefore may be different than the predicted tides. Storms generate the highest tides. High-pressure air masses (fair weather) lower sea level and tides, whereas low pressures raise sea level and tides. Wind effects may be most pronounced in microtidal estuaries (i.e., tidal range less than 2 m). Winds blowing onshore produce higher water levels (setup), while offshore winds generate the lowest water levels (setdown). In these estuaries, tide levels often do not exhibit a regular or predictable pattern. The wind effect on the tides is related to the orientation of the water body relative to the direction of the wind and wind strength and persistence. Strong winds may keep water in the estuaries for days and flood the coastal marshes for longer periods than one would expect from predicted tides (Fig. 4). Of course, hurricanes with over 160.9 km/h winds generate the highest tides (“storm surges”) in local areas, e.g., Katrina – up to 10 m along the Mississippi coast (Fritz et al. 2007). Storm surges move coastal waters inland for considerable distances; Katrina’s surge penetrated at least 10 km along the coast and up to 20 km in Mississippi bays and rivers. The longer the water remains upstream, the greater the ecological impact of salt water intrusion and prolonged inundation on coastal wetlands.

Wind tides and river discharge play a more significant role influencing wetland hydrology of Mississippi Delta marshes than do astronomical tides. These deltaic marshes are flooded at different frequencies than are typical salt marshes. Inland portions are inundated for an average of 16–27 h as much as 263 times per year, while streamside levee marshes (5.1–7.6 cm higher in elevation) are flooded only 160 times for an average duration of 6.6 h (Gosselink 1984). These marshes are flooded for 50% and 12% of the year, respectively, and for more than 80% of the time in September and October.

River discharge significantly affects water levels and salinity patterns in estuaries. Heavy runoff from contributing watersheds can raise water levels in estuaries and move the salt wedge seaward while droughts and low discharge have the opposite effect and introduce salt water into tidal freshwater wetlands. High discharge occurs in spring during peak runoff and in late summer during the hurricane season. These discharges temporarily reduce the daily tidal range in local areas as their flows overwhelm the tides. Peak discharges by the world’s major rivers like the Mississippi

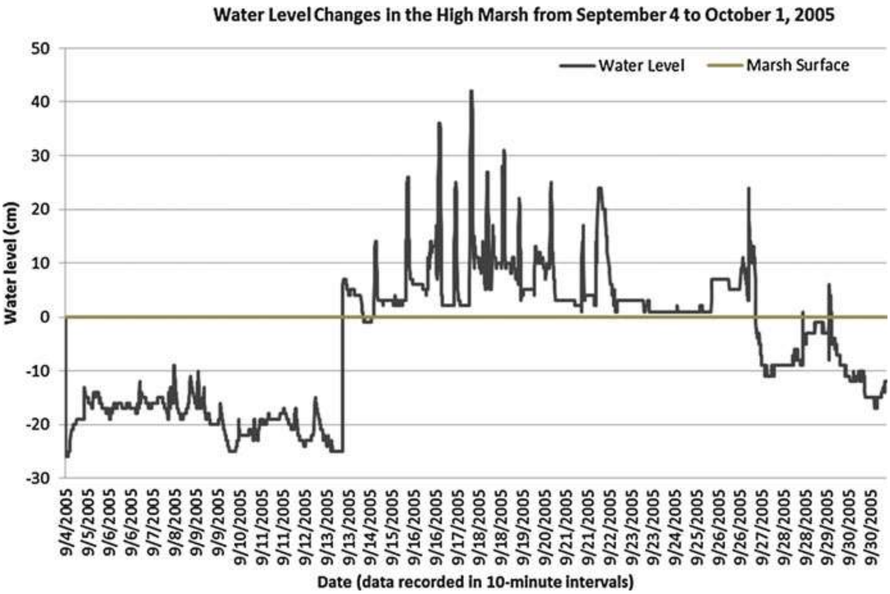

Fig. 4 Water levels in the high marsh are affected by astronomic tides modified by local weather conditions and other factors. This hydrograph shows changes in water levels in a Massachusetts high salt marsh during the month of September 2005. Notice prolonged inundation from 9/13 to 9/27. The plant community was dominated by *Spartina patens* and *Juncus gerardii* (Source: Robert Vincent, used with permission)

River may eliminate tidal influence along its waterway. Precipitation brought about by hurricanes can quickly raise water levels especially in coastal rivers and in estuaries with low tidal ranges that receive freshwater inflow from major river basins. The combined effect of three hurricanes (Dennis, Floyd, and Irene) in September and October 1999 raised river levels significantly, causing almost 2 months of flooding in most of eastern North Carolina (Bales et al. 2000). In areas of Mediterranean climates, winter precipitation may contribute to higher tidal levels during those times.

Global climatological events related to warming and cooling of the tropical Pacific Ocean (El Niño/La Niña-Southern Oscillation, ENSO) also affect the hydrology of coastal wetlands in some places. Pacific warming (El Niño) brings more precipitation to central-southern California, the Southwest, and the Southeast, thereby increasing river discharge and marsh flooding. The cooling event (La Niña) produces drier conditions in the Southwest and Southeast with less frequent and shorter duration flooding of their coastal wetlands (Childers et al. 1990). Interestingly, La Niña brings wetter conditions and higher water levels to the Pacific Northwest. These warming or cooling periods may last for 7–9 months or more and occur on average every 5 years.

Changes in Sea Level

Seasonal and annual shifts in sea level also play a role in tidal wetland flooding. The lowest levels occur in winter and highest levels in summer or early fall due to a combination of factors including thermal heating (decreases water density thereby increasing water volume), precipitation, and increased discharge of freshwater (spring to summer). Monthly sea levels also experience interannual variability.

Tidal Influence in Freshwater Rivers and Their Wetlands

In coastal rivers with large contributing watersheds and high discharge, eventually an upstream location is reached where the water is strictly fresh, with no trace of ocean salts, yet the water levels still fluctuate with the tides. This point marks the beginning of the zone where tidal freshwater wetlands are found. Flood tides cause water levels to rise in these areas. A directional change in the water flow occurs in the lower freshwater tidal areas with water moving upstream during the flood tide and downstream during ebb tide. This area is called the "point of tide reversal." Tidal influence, however, extends farther upstream, where downstream flow continues while water levels temporarily rise due to high tide conditions downstream. Upstream of this area where the water levels are not affected by the tides marks the beginning of the nontidal reach of the river. The National Ocean Service considers the point where the mean tide range is less than 6 cm to be the "head of tide" (Hicks et al. 2000).

Flooding of tidal swamps may be more complicated in the lower reaches (closer to the estuary) since their topography often consists of a mosaic of hummocks (mounds) and hollows (depressions). In contrast, tidal swamps near the upper limits of tidal influence typically have a relatively flat floodplain form. The hollows are frequently inundated as much as once or twice daily and when not flooded remain saturated near the surface, largely due to the short duration between inundations (Rheinhardt 2007). As expected, hummocks are flooded less often, by spring tides and other high-water events, but have water tables close to the surface. The upstream floodplain tidal swamps are flooded by spring freshets, spring tides, and storm surges. Peak river discharges – spring freshets – may eliminate any tidal signal in the water levels and inundate the wetlands for extended periods. Water levels in some swamps can be higher than that of adjacent rivers due to rainfall, residual floodwater, or groundwater contributions (Light et al. 2002). For a detailed description of the hydrology of southern tidal swamps see Day et al. (2007).

Soil Saturation

Water brought in by tides moves both as "sheet flow" across the wetland surface after the tide overtops creek or ditch banks and as "subsurface flow" through the soil saturating aerated portions of the soil. The position of the water table and duration of saturation vary due to many factors including tide stage, duration between flooding events, soil type, topography, geomorphology, groundwater interactions, evapotranspiration, precipitation patterns, and distance from tidal creeks. In Bay of Fundy macrotidal marshes, many of these elements have been reported to be more important than tide height as drivers of subsurface hydrology (Byers and Chmura 2012).

Tides have a significant effect on subsurface hydrology of marshes near the creek banks. Interstitial water (water stored in marsh soils during high tide) seeps from creek banks and drains via tidal creeks at low tide (Jordan and Correll 1985). This soil water is replaced by incoming tides and then lost again with ebb tide, resulting in a fluctuating water table in the high marsh, especially areas in close proximity to the creek banks. This type of seepage ceases during high tide when the marsh is submerged and hydraulic pressure is equal between the creek banks and marsh.

Soil saturation of nonflooded portions of the marsh is affected by the tides to some degree. In a Massachusetts salt marsh, the tidal signal from the semidiurnal tides was observed as water fluctuation in the water table within 2.5–15.0 m of a tidal creek; howevever, beyond 15 m, there was no horizontal movement of water (Nuttle 1988). Similar results were found in a New York brackish marsh where the high tide signal could still be detected in the water table up to 12 m from the creek (Montalto et al. 2006). The water table remained high in the interior marsh longer than in the creekside marsh. At a distance of 6 m from the creek, the soil was saturated to within 20 cm of the surface more than 90% of the time during a lunar month, whereas the water table of the marsh closer to the creek had a water table at this depth for only half of the time. Beyond 24 m from the creek, the interior marsh was saturated to the surface for more than 90% of the time.

Groundwater Interactions

Groundwater may enter coastal wetlands from unconfined aquifers through the marsh substrate or tidal creeks that breech the confining layer. Along the upland border, groundwater discharging to the surface may create seepage areas where freshwater species may occur. Groundwater discharge may also affect salinities further into the marsh. In a South Carolina marsh, less saline conditions (5–10 ppt) were found in areas receiving considerable groundwater (Gardner et al. 2002). Vegetation shifted from glassworts (*Salicornia* spp.) in the neighboring saline areas (25–50 ppt) to black needlerush (*Juncus roemerianus*) in the groundwater-affected marsh.

Wetland Zonation Driven by Hydrology

Tidal wetlands are intertidal habitats, which are alternately flooded and exposed to air. Given the variable levels of flooding by daily, spring, neap, and storm tides, the elevation within the wetland largely determines the frequency and duration of flooding. Several "water regimes" have been used to describe the hydrologic zones of tidal wetlands for classification and inventory purposes (Cowardin et al. 1979). For marine and estuarine wetlands where tides are the main source of water, three water regimes are applied including irregularly exposed, regularly flooded, and irregularly flooded (Fig. 5). The irregularly exposed zone is the area that is nearly permanently flooded but exposed during spring low tides (from mean low water – MLW – to extreme low water of spring tides). The irregularly exposed zone represents the lowest portion of tidal flats. The regularly flooded zone is typically flooded at least once daily by the tide. It extends from MLW to the mean high tide mark (MHW) and is occupied by the low marsh and the majority of tidal flats. The irregularly flooded zone is flooded less than once per day and occurs from MHW to extreme high water of spring tides. This zone has the most varied hydrology ranging from almost daily flooding to areas flooded only by spring or storm tides. This zone is the high marsh where a diversity of plant communities may form depending largely on variations in hydrologic and salinity conditions (Table 1). Depressions in the high marsh are flooded by spring and storm tides and water will persist for variable periods, with pools being inundated for the longest periods and pannes for shorter periods. In semiarid, arid, and tropical areas, barren areas ("salinas") may form within the irregularly flooded zone. Along the US coast, salt marshes are mostly irregularly flooded (high marsh) types, yet regularly flooded types predominate the marshes behind the sea islands of South Carolina and Georgia and in coastal Louisiana where significant subsidence is occurring.

For tidal freshwater wetlands, overbank flow from rivers plays a significant role in their hydrology. While some of these wetlands are regularly flooded like their estuarine counterparts, the focus of others is on river overflow. The duration of flooding in tidal freshwater wetlands depends on both tidal and inland water influences and are described as: semipermanently flooded-tidal (flooded throughout

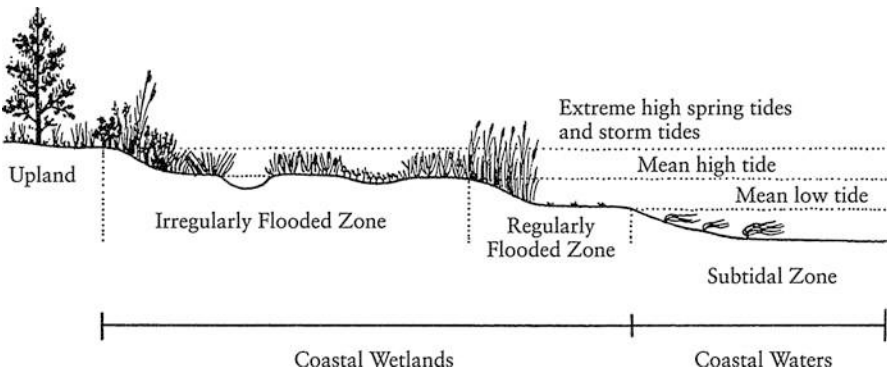

Fig. 5 Two main zones of coastal wetlands created by flooding frequency: regularly flooded and irregularly flooded. The irregularly exposed zone (not shown) occurs between the regularly flooded zone and subtidal zone where spring tides expose shallow bottoms but can be exposed by strong offshore winds (Copyright: Tiner 2013)

Table 1 Flood frequency and salt marsh plant communities (Sources: RI – Bertness and Ellison 1987; GA – Antlfinger and Dunn 1979; CA – Cahoon et al. 1996)

Plant community	State	Average days/month subject to flooding
Spartina alterniflora – tall form	RI	30.5
S. alterniflora – short form	RI	23.5
Spartina patens	RI	17.3
Juncus gerardii	RI	8.7
S. alterniflora – tall form	GA	24.4–30.5
S. alterniflora – short form	GA	12.2–24.4
Barren zone	GA	1.5–3.1
Salicornia spp. – *Batis maritima*	GA	1.2–2.4
Juncus roemerianus – *Borrichia frutescens*	GA	0.6–1.5
Spartina foliosa	CA	30.5
Salicornia depressa	CA	5.0–6.0

the growing season in most years), seasonally flooded-tidal (flooded for extended periods during the growing season), and temporarily flooded-tidal (flooded for brief periods usually a week or less during the growing season) (Cowardin et al. 1979).

Impacts to Coastal Wetland Hydrology

While many tidal wetlands are freely connected to the ocean or estuaries, the hydrology of many others has been altered either directly or indirectly. Direct alterations involve onsite impacts including ditching, diking, and filling, whereas indirect effects are produced by activities offsite (see Tiner 2013 for details). Many tidal marshes have been ditched, first to improve drainage for salt hay farming or livestock usage, then later for mosquito control. Building causeways across marshes for roads and railroads has restricted both sheet flow and tidal inflow to the marsh by the installation of culverts, tide gates, or narrow bridges, which may reduce the volume of water entering the wetland complex. Impoundments have been constructed in tidal wetlands for waterfowl management, mosquito control, or other purposes. Water-control structures (e.g., tide gates or weirs) are installed to regulate water levels within these diked wetlands. Tidal wetlands have been fragmented by development (e.g., harbor facilities, airports, residential and commercial real estate), which in addition to reducing marsh extent has altered the quality of many wetlands through disrupting tidal flows and pollution. Offsite alterations of estuarine hydrology have significant impacts on tidal wetlands. For example, deepening of rivers for navigation has increased the volume of water entering estuaries, elevated tidal ranges, heightened tidal current velocities, and allowed salt water to migrate further upstream. These changes have increased bank erosion and impacted wetland plants and animals. Freshwater diversion projects including heavy use of fresh water for industrial purposes and damming rivers for water supplies have had similar impacts. Coastal wetland restoration efforts typically focus on restoring hydrology because many of the problems they seek to address (e.g., invasive species, restricted access to marshes by fish and aquatic invertebrates) are the result of altered hydrology.

Future Challenges

Rising sea-levels will undoubtedly have an enormous impact on coastal wetlands depending on if the marshes can accrete their marsh platform to support plants. Increased air temperature and carbon dioxide availability and changes in precipitation patterns will also affect vegetation growth. Much has been written on the predicted fate of tidal and other wetlands in response to climate change (see Cahoon et al. 2006; Lovelock and Ellison 2007; Kirwan et al. 2010; Parker et al. 2011). Recent observations have already witnessed changes from low marsh to tidal flats or subtidal bottoms, high marsh to low marsh, and salt marsh migration into low-lying forests as a result of changes in the frequency and duration of tidal flooding. Similar changes in mangroves are expected.

Contents

Abstract

This chapter provides a brief compilation of reference works on hydrologic modeling of wetlands. Hydrology, which is the study of water circulation and its constituents through a water cycle on or near the land surface, is the primary driving force determining the structure and functions of wetlands. Developing a robust wetland model requires understanding the main hydrologic processes occurring in its drainage area. Succinct discussions of hydrologic model types, simulation models for wetland hydrology, and key modeling considerations are presented here.

Definitions

Definition: Riverine Wetland Hydrology

Author: Beth Middleton

Riverine wetland hydrology is characterized and driven by seasonal changes in precipitation, snow melt, groundwater input/output, and evapotranspiration. River hydrology also reflects geomorphology (e.g., depth to groundwater/bedrock and constraints by channel walls). Rivers in more arid parts of the world tend to have "flashier" flow during rainy season, but little streamflow during the drier season of the year.

Definition: Water Monitoring

Author: Beth Middleton

(*continued*)

Water monitoring is the measurement of water level changes in wetlands using instrumentation such as water gages. In conjunction with a nearby water gage, a Sediment Elevation Table (SET; pictured) is useful to construct a simple hydrograph of a research site. During major flooding, regional sites at the same elevation are inundated to similar depths by the floodwater sheet. This idea can be used to tie recorded water depth fluctuation at water gages near SETs in research sites. A SET establishes a stationary monument, which consists of a series of connected rods driven into the ground to the point of refusal.

Construction of a Sediment Elevation Table, which is useful for understanding elevation and hydrologic changes in wetlands. Pictured are Guodong Wang and Evelyn Anemaet. Photo by Beth Middleton

Introduction

Hydrology is a science concerned with the circulation of water and its constituents through a water cycle, including precipitation, evaporation, runoff, infiltration, groundwater flow, streamflow, and the transport of substances dissolved or suspended in the flowing water (Maidment 1992). It specifically deals with water on or near the land surface. In wetlands, hydrology is the primary driving force, affecting their structure and functions. The existence of wetlands is governed by a continuous or recurrent presence of surface or subsurface water, occupying transition zones between predominantly wet and dry environments and thereby sharing aspects of both aquatic and terrestrial ecosystems (USEPA 2008). Wetland restoration or creation efforts are attempting to mimic this necessary hydrologic environment for the desired wetland type (Demissie et al. 1997).

Wetlands can be broadly categorized into two classes based on topographical location in the landscape and hydrologic factors: nontidal or inland wetlands (e.g., riverine wetlands) and tidal or coastal wetlands (e.g., fringe wetlands). The focus of this chapter is on modeling the hydrology of nontidal wetlands, which requires understanding hydrologic processes occurring in the wetland drainage area as well. Its main objective is to provide a concise compilation of reference works on hydrologic modeling of wetlands. In doing so, types of hydrologic models, models used for simulation of wetland hydrology and important modeling considerations are succinctly discussed.

Modeling of Wetland Hydrology

Hydrology is one of the most important features used in defining wetland structure and function, in addition to soil and vegetation. Inland wetlands predominantly occur in regions where precipitation is in excess of evapotranspiration, exhibiting seasonal fluctuation of water surface levels dependent on weather and antecedent moisture conditions. Based on the recurrence of flooding, wetlands could be intermittently, seasonally, or permanently flooded (William and Gosselink 2000). The hydrologic water budget of a wetland comprises wetland storage, inflows and outflows, and mathematically can be expressed as

$$\frac{\Delta S}{\Delta t} = I - O\ ;\ \text{where } I = P + SR + GD \quad \text{and} \quad O = ET + SO + GR$$

Where I is defined as inflows to the wetland such as precipitation (P), surface runoff (SR), and groundwater discharge (GD); O is defined as outflows from the wetlands including evapotranspiration (ET), surface outflow (SO), and groundwater recharge (GO); and ΔS is defined as water storage in the wetland at a given time (Δt). Figure 1 illustrates the major components of the wetland water budget, including precipitation, surface water inflows and outflows, groundwater, and evapotranspiration. The precipitation pattern varies with climate regions where there exists distinct periods of dry and wet seasons. Surface water inflows and outflows can be channelized or overland flows, and often match with precipitation patterns with the exception of spring thaw conditions. Evapotranspiration depends on the meteorological, physical, and biological conditions in the wetlands and has a seasonal pattern with highs in summer and lows in winter (William and Gosselink 2000).

Understanding wetland hydrology requires gathering all data that are important to describe components of the hydrologic water budget as accurately as possible. Precipitation including both rainfall and snow is usually a point measurement from which areal coverage is estimated. Point measurements are subject to errors as a result of

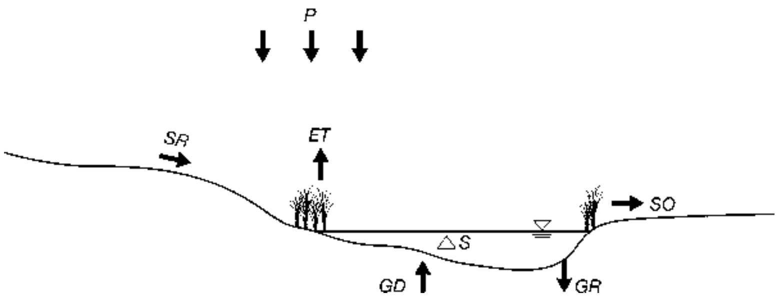

Fig. 1 Components of wetland water budget with inflows including precipitation (*P*), surface runoff (*SR*), and groundwater discharge (*GD*) outflows including evapotranspiration (*ET*), surface outflow (*SO*), and groundwater recharge(*GO*). ΔS is water storage in the wetland at a given time

wind eddies created by the gage and estimated areal precipitation values could introduce additional uncertainties. Surface inflows can be estimated as a function of hydrologic processes in the wetland drainage area, including surface and subsurface runoffs. Appropriate characterization of the wetland drainage area is required for accurate runoff simulations. Surface outflows may be estimated as a function of wetland storage levels and thus requires adequate collection of data to establish wetland storage-outflow relationships. Groundwater inflows or outflows depend on the relative water level in the wetland and the surrounding groundwater table. Groundwater flows into a discharge wetland when the surrounding water table is higher and the reverse is true for a recharge wetland. Data collection and analysis are crucial steps for accurate representation and thereby modeling of wetland hydrology.

Important Modeling Considerations

Ideally, modeling of wetland hydrology should include the ability to simulate precipitation, surface runoff, infiltration, groundwater flow, wetland storage, outflows, and routing overland flow, streamflow, and subsurface flow (USACE 1988). The importance of hydrologic simulation components may vary depending on the purpose of the modeling. When the focus of interest is in the wetland hydrologic budget and functions, it is necessary to perform detailed modeling of all hydrologic components. In contrast, hydrologic processes such as evapotranspiration, infiltration, and groundwater flow may not be significant in the model during flood simulations. Therefore, identifying important component processes is central to effective modeling exercises. For example, in their modeling effort to evaluate the cumulative hydrologic impacts of wetlands in watersheds, Demissie et al. (1997) first identified important component processes to be considered, which included interception, evapotranspiration, infiltration, drainage, overland flow, groundwater flow, and channel routing.

Before selecting a model to simulate wetland hydrology, understanding its characteristic features such as model structure and process components, spatial and temporal representation, and application extent are all very important. A modular programming structure consisting of components for subprocesses, data input and response output facilitates simpler model application, potential coupling and/or modification without affecting the model structure. A model with distributed-parameter representation provides the capability to account for spatially varied hydrologic responses with in a watershed. The ability to perform continuous model simulation is desirable as it enables simulating changes in soil moisture storage. Such capabilities could also be critical in assessing water availability for wetland recharges during low-flow conditions and estimating initial soil moisture conditions in cases of single-event simulations. A model's application extent should include the possibility of simulating watersheds with varying landscapes such as farmland and forest where wetlands mostly occur, and also urban areas. Finally, detailed model documentation describing process components and program structure is necessary for an effective modeling exercise.

Mathematical Hydrologic Model Types

Types of hydrologic models can be distinguished by the way in which the component processes are modeled. Major classification of mathematical hydrologic models generally includes four categories: deterministic or stochastic models; empirical, physically based, or conceptual models; lumped-parameter or distributed-parameter models; and continuous-time or event-based models. A deterministic model entails defined initial conditions that are parameterized while excluding randomness. In contrast, a stochastic model accounts for randomness resulting from uncertainties in model parameters. Based on a representation of concerned physical processes, a model can be classified as "empirical" when it is derived from experimentation or dependent correlations of observed hydrologic outputs to inputs, "physically based" when it is based on governing laws of physics including conservation of mass, momentum, and energy, and "conceptual" when it represents the hydrologic system in simplified conceptual elements. A hydrologic model can be categorized as "lumped" when it involves spatially aggregating parameters of the hydrologic system to create uniformity and as distributed when it accounts for spatial and temporal variability of both input and output of hydrologic variables. Hydrologic models can also be classified as "event-based" if they are designed to simulate a single event from a couple of minutes to days, or as "continuous-time" models if they are capable of performing long-term simulations.

Hydrologic Models Used for Wetland Simulation

A number of hydrologic models have been developed and applied to simulate wetland hydrology. Comprehensive reviews of mathematical hydrologic models as applied to the simulation of wetland hydrology were discussed by several researchers, providing insights into model strengths and weakness in terms of simulating hydrologic processes and functions (Bengston and Padmanabhan 1999; Demissie et al. 1997). An overview of selected hydrologic models that were used for simulation of wetland hydrology is provided here.

The Iowa State University Hydrologic Watershed Model (ISUHM; Haan and Johnson 1968), the Minnesota Model for Depressional Watersheds (MMDW; Moore and Larson 1979), and DRAINMOD (Skaggs 1980) were among the first of these models that were specifically developed to analyze wetlands and agricultural drainage. These physically based models are capable of simulating hydrologic processes including precipitation, surface runoff, evapotranspiration, infiltration, and streamflows. Depressional storage and routing are used in ISUHM and MMDW to simulate the effect of wetlands. In contrast, DRAINMOD simulates wetland effects by filling available depression storage volume before initiating surface runoff and DRAINMOD also allows seepage of water stored in the depression. ISUHM, an event-based model, was later modified to enable continuous simulation (Campbell and Johnson 1975). DRAINMOD was also upgraded to perform watershed modeling by incorporating an unsteady-flow, channel-routing procedure based on the dynamic wave method (Broadhead and Skaggs 1984).

Walton et al. (1996) developed the Wetlands Dynamic Water Budget Model to evaluate hydrologic and hydraulic processes in various types of wetlands. The model consists of modules for simulating surface water, ponding and infiltration, and ground water processes. Application of the model to Cache River wetlands in Arkansas confirmed that backwater effects of downstream constrictions resulted in an inundation of upstream wetlands.

In an effort to simulate the effect of wetlands on flooding, Ogawa and Male (1986) applied HEC-1 (Feldman 1995) and employed its reservoir routing option, representing wetlands as reservoirs. Nichols and Timpe (1985) applied Hydrologic Simulation Program-Fortran (HSPF; Donigan et al. 1995) to simulate wetland hydrology in their study of phosphorus dynamics in floodplain wetlands in South Florida. The HSPF model was modified to better simulate wetlands by including a flow routing algorithm based on depth-discharge relationships for the wetlands. Arnold et al. (2001) developed a water budget model for wetland simulation, incorporating it into the hydrologic model, Soil and Water Assessment Tool (SWAT; Arnold et al. 1998). Modification to SWAT model allowed effecting limited interaction of water stored in the wetland with the soil profile and the shallow aquifer. Bekele et al. (2011) applied SWAT to simulate hydrologic and water quality functions of constructed wetlands in an attempt to identify optimal wetland locations in the tributary watersheds of Mackinaw River in Illinois that are predominantly agricultural. In that study, the constructed wetlands were considered as best management practices for controlling nonpoint source pollution.

Sun et al. (1998) developed FLATWOODS model to simulate the hydrology of cypress wetland-pine upland landscape by coupling a 2-D groundwater model, a surface flow model based on a variable source hydrology, an evapotranspiration model, and an unsaturated water flow model. The model is capable of simulating daily groundwater table depth, evapotranspiration, and soil moisture content distributions in a watershed and it is applied to pine flatwoods research watersheds in northern Florida. The FLATWOODS model may be used to predict hydrologic impacts of various forest management practices in coastal regions. The FLATWOOD model, however, is limited in its description surface water-groundwater interaction because of its large spatial scales and model structure (Mansell et al. 2000).

WETLANDS (Mansell et al. 2000) is a model developed to simulate wetland hydrology, and it is a modified version of USGS's Variably Saturated Two-Dimensional Transport model (VS2DT; Healy 1990). Major modifications to VS2DT include incorporating capabilities to simulate a surface pond with seasonally dynamic water levels over inundated areas, estimate evapotranspiration using limited data, and simulate surface water-ground water interaction. The modified model was used to successfully simulate local hydrology for a cypress pond located in a coastal plain, pine forest landscape, describing temporal patterns of daily pond water and groundwater table elevations. Even in cases in which available empirical data for a given site are minimal, WETLANDS has the potential to be utilized as a predictive tool for wetland hydrology provided that appropriate assumptions were made (Mansell et al. 2000).

Coupling components from various models and/or modification of process routines within a model have become commonplace when a single suitable model is unavailable. In this regard, Yergeau (2010) developed a hydrologic model, which coupled the Storm Water Management Model (SWMM; Rossman 2005) with MODFLOW (McDonald and Harbaugh 1988) to simulate the hydrologic water budget for Kearny Marsh to understand the dynamics of urban wetland hydrology for potential restoration efforts. The coupling was done through an exchange of evapotranspiration and infiltration data between the models. Thompson et al. (2004) developed a coupled hydrologic-hydraulic model using MIKE SHE (Refsgaard and Storm 1995) and MIKE 11 (Havnø et al. 1995) modeling system for lowland wet grassland, the Elmley Marshes, in southeast England. The marshes have characteristic features of wetlands commonly found in Europe with a complex ditch network and water control structures. The coupled model was able to simulate seasonal fluctuation of groundwater and ditch water levels, and it could be used to explore the impact of alternative water level management (Thompson et al. 2004). Demissie et al. (1997) developed an integrated model for evaluating cumulative hydrologic effect of wetlands in Cypress Creek watershed in the Cache River basin in southern Illinois. This wetland hydrologic model was built on Areal Nonpoint Source Watershed Environment Response Simulation (ANSWERS; Beasley and Huggins 1982), which is a physically based, distributed-parameter, event-based hydrologic model, by incorporating dynamic wave channel-routing component.

Challenges

Hydrologic modeling of wetlands involves the process of selecting and/or developing models that are appropriate for a particular application of interest. This process should take into account the tradeoff between model complexity and accuracy. After reviewing complexity, accuracy, and effectiveness of mathematical models applied to freshwater wetlands, Costanza and Sklar (1985) concluded that there is an optimum model complexity beyond which the benefits of additional articulation are outweighed by declining accuracy. Therefore, the challenge for modelers is to strike a balance between model complexity and accuracy in developing and/or selecting the right model for simulation of wetland hydrology.

Contents

Abstract

Constructed wetlands are now widely used around the world for water treatment. The Everglades Stormwater Treatment Areas (STAs) are currently the largest constructed wetlands and are reducing Total Phosphorus (TP) concentrations in agricultural and urban runoff that flows into the Everglades. Average inflow flow-weighted TP concentration is 140 ppb and an average of 73 percent removal efficiency is observed from all the STAs. Total area of the STAs is 27,530 ha and target water depth is 38-46 cm.

Definitions
Definition: constructed wetland

Author: Beth Middleton

A constructed wetland is an artificial wetland built for a specific purpose, e.g., a wetland created to improve the water quality of sewage water. Such wetlands are often planted with emergent species such as *Typha* spp. or *Phragmites australis*.

Introduction

Constructed freshwater wetlands are being used to reduce phosphorus (P) concentrations in surface waters that flow into the Everglades, a 900,000 ha subtropical freshwater marsh located in the southern end of Florida, USA. (Fig. 1).

Emergent species are often planted in constructed wetlands. Photo by Beth Middleton

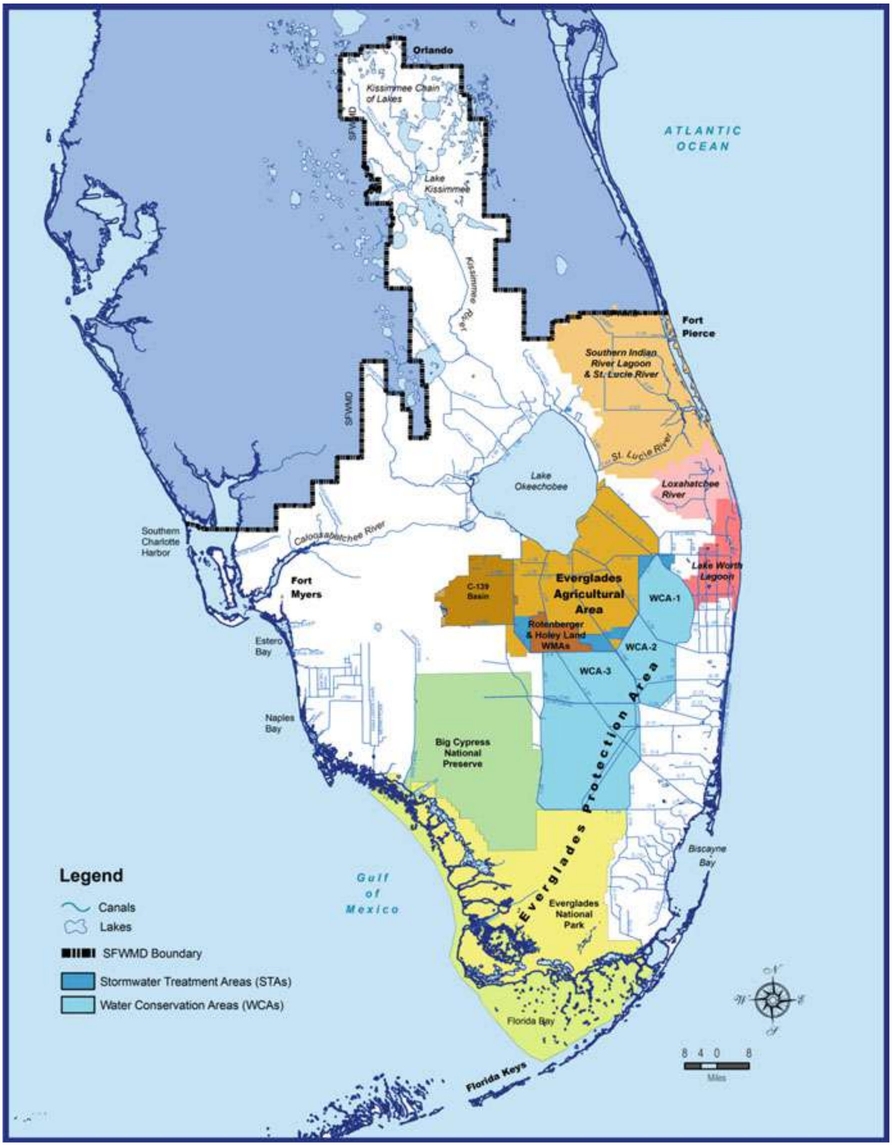

Fig. 1 The Everglades Agricultural Area, Stormwater Treatment Areas, and the Everglades Protection Area

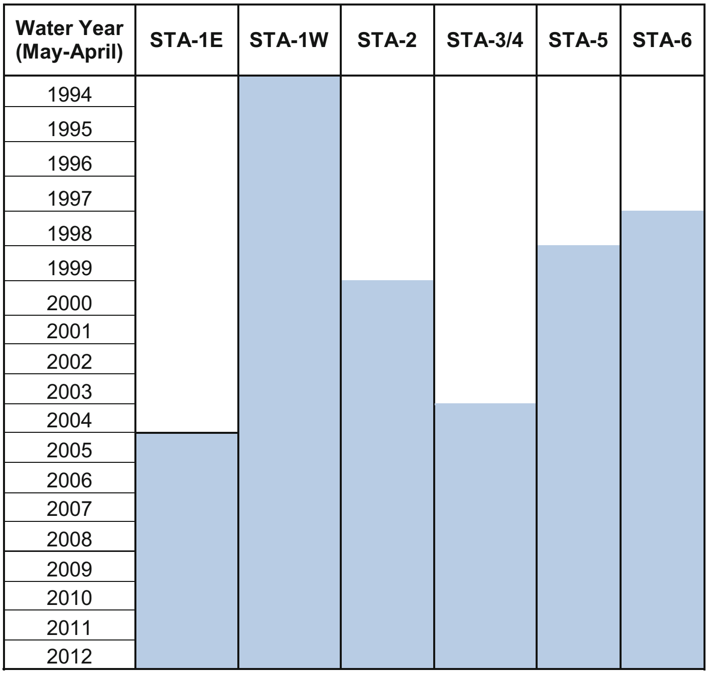
The Everglades ecosystem has been impacted by both anthropogenic and natural factors through the years. Observed changes in flora and fauna are attributed to increase in nutrients in inflow waters and hydroperiod changes (Davis 1991; Koch and Reddy 1992; Noe et al. 2001; Ramesh and DeLaune 2008). In the twentieth century, the northern portions of the Everglades swamps were drained with an

Fig. 2 Stormwater Treatment Areas, STA-1E, 1-W, 2, 3/4, 5, and 6 showing emergent aquatic vegetation (EAV) and submerged aquatic vegetation (SAV) cells

intricate canal network and pumps, to create a very productive agricultural basin, called the Everglades Agricultural Area (EAA). Currently, the EAA is a 224,000 ha irrigation/drainage basin upstream of the remaining Everglades (Fig. 2). The main crop in the EAA is sugarcane as well as vegetables, rice, and sod. The EAA basin currently has a lower elevation than the surrounding areas due to subsidence of muck (organic) soil as a result of drainage, with a loss of as much as 1.7 m in 80 years (1924–2003; Snyder 2004). Irrigation water to the EAA is supplied from Lake Okeechobee. Excess rainfall is drained from the agricultural fields as runoff/drainage and is mostly pumped to the south, with agriculturally influenced water quality with a high nutrient content. For the past two decades, the Everglades Stormwater Treatment Areas (STAs) (Fig. 2) in combination with agricultural Best Management Practices (BMPs) have performed an important role in improving water quality in discharges to the Everglades (Baker et al. 2012).

Currently, six constructed wetlands with a total area of 27,530 ha are operational. The objective of this chapter is to present hydrologic and phosphorus removal performance of these Everglades STAs.

Table 1 Operational timeline for the Everglades STAs



The Everglades Stormwater Treatment Areas

Natural wetlands have been used to treat water for at least a century. Construction of wetlands for water treatment started in the 1950s. Constructed wetlands are now widely used around the world to remove pollutants from water (Kadlec and Knight 1996; Kadlec and Wallace 2009), including the construction of the Everglades STAs in the past two decades. These STAs with a total area of 27,530 ha are currently the largest manmade wetlands in the world. These wetlands are designed and operated to discharge low TP concentrations, originally designed for 0.05 mg L^{-1} outflow TP concentration and currently achieving lower concentrations. The first of these six STAs started operation in 1994, and the others have come on line since then (Table 1). Each STA is compartmentalized into cells and in most cases the cells are aligned serially to form treatment paths called flow-ways. The six original STAs, STA-1E, STA-1 W, STA-2, STA-3/4, STA-5, and STA-6, are shown in their current states in Figs. 3, 4, 5, 6, and 7. (Note that STA-5 and STA-6 have recently been combined, but their performance records to date are separated for reporting). The cell

areas shown on the STA maps were calculated from levee centerlines and do not include inflow canals. The area of most of the STAs was increased in later years. The hydraulics of the STAs commonly require supply canals, inflow and outflow pumps, flow distribution canals, divider levees, gated culverts, and flow collection canals. The vegetation type of each cell is related to its position along the treatment path (Figs. 3, 4, 5, 6, and 7).

The cells are populated with a mixture of plant species. In general, upstream cells which receive influent water with high TP are dominated by emergent aquatic vegetation (EAV) species. Downstream cells are usually dominated by submerged aquatic vegetation (SAV), which provide further TP reduction. The common vegetation species in the STAs are listed in Tables 2, 3, and 4. Vegetation varies among the cells and each cell undergoes temporal changes in vegetation coverage and composition. Figure 8 depicts vegetation in four STA cells to show variations in species coverage.

From 1996 to 2012, these constructed wetlands retained approximately 1,560 metric tons (mt) of TP, reducing inflow loads by 73%. Over this period, the inflow flow-weighted TP concentration of 140 parts per billion (ppb) was reduced to an outflow flow-weighted concentration of 37 ppb (Table 5). The TP removal rate ranges from 50% to 90% varying over the period of operation from one STA to another and from year-to-year in each STA (Pietro 2012). Sources of variation include STA site characteristics such as soils, vegetation, topography, hydraulic

and TP loading rates, site geometry, cell configuration, and operational history. Internal P retention and cycling processes are likely to be important and research on internal processes is being planned.

Stormwater Treatment Area Design

Wetlands remove phosphorus via sediment accretion, leaching, vegetation growth and decay, and microbial activities (Kadlec and Knight 1996; Ivanoff et al. 2013). The ability of wetlands to assimilate and store phosphorus is the basis of their utility for treating surface water delivered to the Everglades. Important parameters for designing and operating constructed wetland treatment systems include inflow TP concentration (C_i), inflow rate (Q), desired outflow TP concentration (C_o), outflow rate (Q_o), settling rate (k), depth (d), and available area of land. The settling rate (k) is developed from existing treatment wetlands (Walker 1995). In developing the design basis for the Everglades STAs, Walker (1995) assumed steady-state flow with sheet-flow hydraulics and first-order kinetics. Phosphorus removal in wetlands is

postulated to be a first-order process where the rate of removal is directly proportional to the amount of TP present as expressed by Eq. 1 (Kadlec and Knight 1996) although the process is complex (Fig. 9).

$$C_o = C^* + (C_i - C^*)\exp\frac{-kA}{0.0365Q} \tag{1}$$

Where C_o and C_i are outflow and inflow TP concentrations in mg L^{-1}, C^* is wetland background TP concentration in mg L^{-1}, k is settling rate in m year^{-1}, A is area in ha, and Q is flow in m^3 d^{-1}. The amount of water a given area of wetland can treat depends on the inflow rate, TP load (inflows and concentrations), and desired outflow TP concentration. The required area (A) for a target outflow concentration for a given inflow and wetland background concentrations and for a given inflow (Q) can be computed from Eq. 1. Area (A) can be derived in a few iterations in a spreadsheet.

Hydrology of the Everglades Stormwater Treatment Areas

The hydrology of the Everglades STAs is dominated by the amount and distribution of basin runoff. Direct rainfall to and evapotranspiration from the wetlands is a small fraction of the mass balance accounting for only about 11% and 12% of total inflows and outflows, respectively. The wetlands are enclosed with earthen levee and some seepage in and out occurs through the levees and vertically from the wetlands.

Hydrologic characteristics of the Everglades STAs are illustrated by Fig. 10, which shows the monthly hydrology of STA-1W from 1999 to 2012. As shown in the figure, inflows and outflows are similar in most cases, so that differentiating between the two lines in the figure is difficult. The water budget of the wetlands is expressed by Eq. 2 and hydrologic parameters are shown in Fig. 9. Equation two is:

$$\Delta S = \text{Inflow} + \text{Rainfall} - \text{Outflow} - \text{ET} \pm \text{Seepage} \pm \varepsilon_{t,} \qquad (2)$$

where ΔS is the change in storage in the wetland from the beginning day to the last day of the period of water budget analysis and ε_t is total error, which is a cumulative term of measurement errors for all the hydrologic parameters and ungauged sources and sinks. The water budget for STA-1W from 1999 to 2012 is depicted in Fig. 11. The change in storage, seepage, and error terms are lumped together and account for only 3.5% of the water budget. South Florida is relatively a wet region with a mean

annual rainfall of 1,340 mm. Drought frequency has increased in the last decade with several years with below average rainfall (2000, 2001, 2006, 2007, 2008, 2011, and 2012).

Precipitation is well-monitored in STA-1 W with six rain gauges through 2010 and currently five rain gauges. Daily rainfall has high spatial variation in the region,

but this relatively dense rain gauge network provides good measurements (Abtew et al. 1995). The wet season from June through October contributes 66% of the annual rainfall, and most of the inflows to the STAs are during this season. During dry periods, there were times when treatment cells dried out so that supplemental water from a lake source was needed to keep the STAs hydrated. When treatment cells dry out and later rehydrate, stored phosphorus can be released to the water column resulting in a temporary decrease in the performance efficiency of the STA.

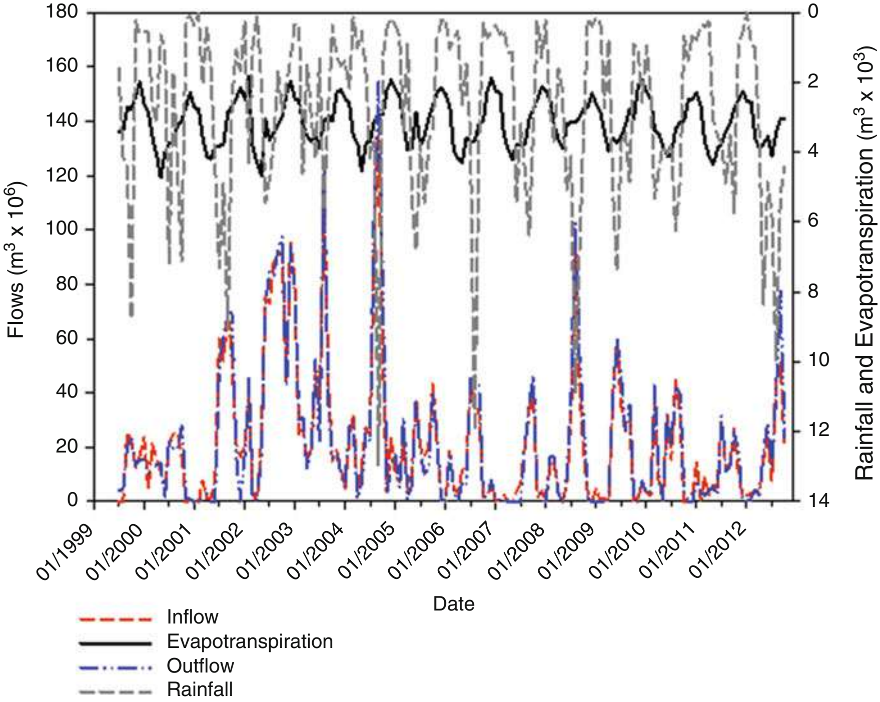

Fig. 10 Monthly hydrologic variation in STA-1W (1999–2012)

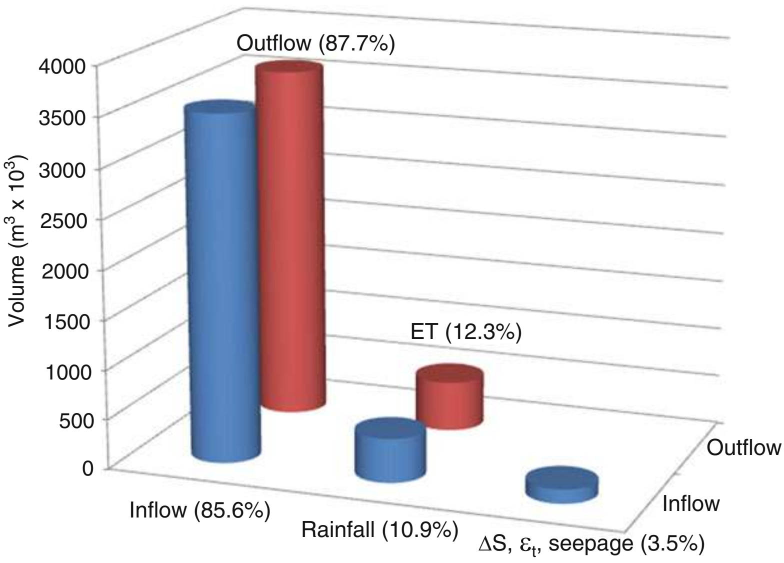

Fig. 11 STA-1W water budget (1999–2012)

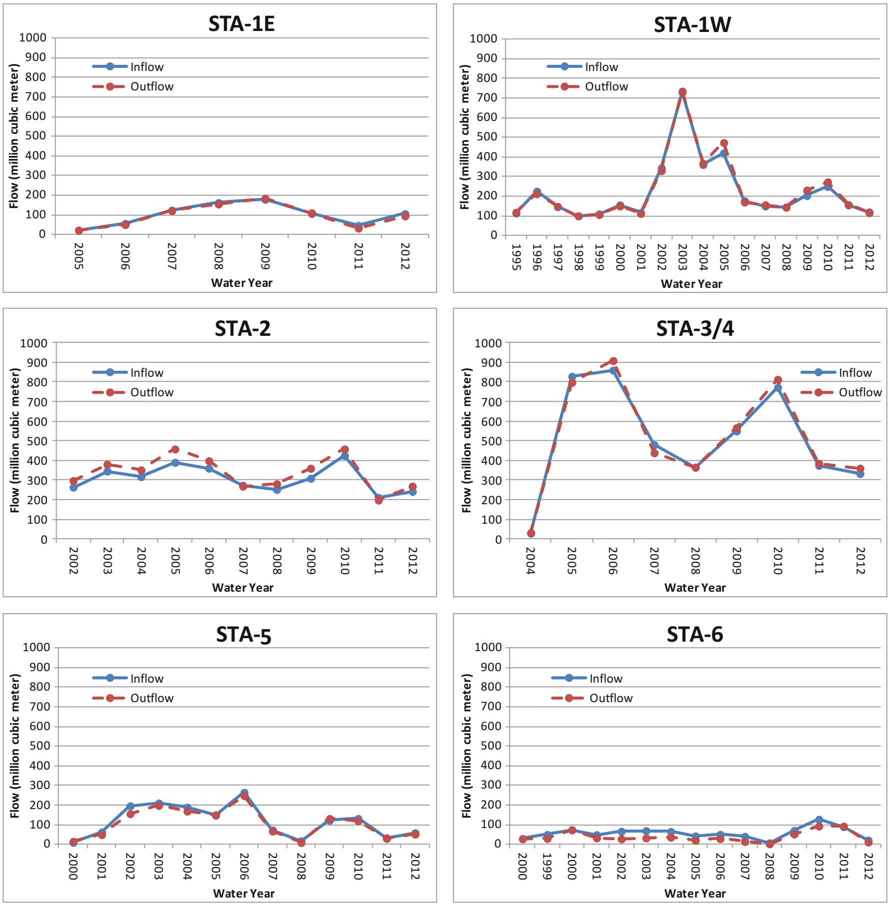

Fig. 12 Annual inflows and outflows for each STA

Wetland evapotranspiration is quantified using an equation that was developed from lysimeter studies in the wetlands (Abtew 1996; Abtew and Melesse 2012). Three different types of lysimeters were installed in cells dominated by cattails, mixed marsh, or open water cells. The study was conducted for 2 years.

Figure 12 depicts annual inflow and outflow from each STA showing that inflow and outflow closely match. Rainfall is a fraction of the water budget, but runoff generated from the rainfall in the upstream basin drives the treatment process. Figure 13 shows the relationship between monthly rainfall in the basin and inflow into STA-1W. Both variables are standardized to a mean of zero and standard deviation of 1 to remove visual distortion of the differences in magnitude and range between the variables.

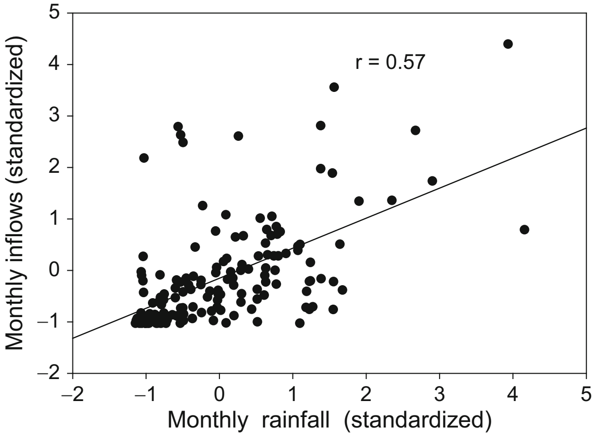

Fig. 13 Correlation between rainfall in the basin and inflows into STA-1W

Stormwater Treatment Areas Operation and Performance

As a major component of Everglades restoration, the STAs were built and are operated to reduce the amount of total phosphorus in surface waters that flow into the Everglades Protection Area (Pietro 2012). The South Florida Water Management District operates the system of STAs with continuous evaluation of their performance and adaptation of operations. The STAs are flow-through systems approximating a plug flow type process rather than a completely mixed reactor type process. STA managers use an adaptive approach and weekly data analyses to make operational decisions. Current water depths in the STAs, outflow TP concentrations, and phosphorus loading rates are considered when making operational decisions for each STA and flow-way. Figure 14 compares inflow and outflow TP concentrations to depict the performance of each STA for its period of operation. The difference in source water TP concentration and the phosphorus reduction efficiency of the STAs is discernible. Tables 5 and 6 depict detail performance of each STA and all STAs combined for period of operation and the 2012 water year (May 1, 2011 to April 30, 2012), respectively. The adjusted effective treatment area is the actual treatment area in water year 2012. These areas vary annually due to many reasons, for example, a cell may be off line for construction or maintenance reasons.

Hydraulic loading rate (HLR) is computed using Eq. 3 as:

$$\text{HLR} = \frac{Qx100}{A}, \tag{3}$$

where HLR is hydraulic loading rate in cm d^{-1}, Q is flow in $m^3\ d^{-1}$, and A is STA area in m^2. Because the length of time that a unit of water resides in the marsh is a factor in TP reduction, hydraulic residence or retention time (HRT) is an important design and operation parameter. It is calculated using Eq. 4 as:.

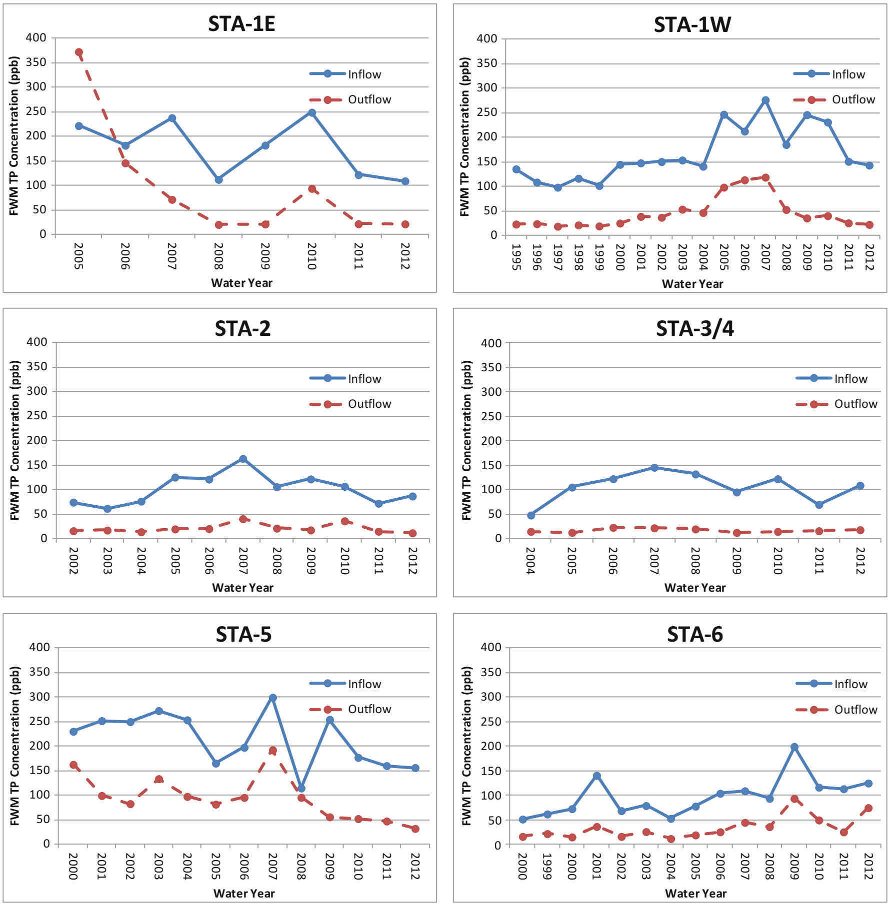

Fig. 14 Inflow and outflow TP concentrations from each STA

$$\mathrm{HRT} = \frac{Ad}{Q^*}, \tag{4}$$

where HRT is in days, A is area in m^2, d is depth in m, and Q^* is average of inflow and outflow in $m^3\ d^{-1}$. TP loading rate is computed as:

$$\mathrm{PLR} = \frac{Q_i C_i}{A}, \tag{5}$$

where PLR is phosphorus loading rate in g m^{-2} $year^{-1}$, C_i is inflow TP concentration in g m^{-3}, Q_i is flow in m^3 $year^{-1}$, and A is area in m^2. Detailed performance parameters for each STA and all STAs for water year 2012 are shown in Table 6. The average TP load reduction for all STAs for water year 2012 was 83%.

Table 6 Performance of STAs (May 1, 2011 to April 30, 2012)

STA Monitoring and Maintenance

Intensive hydrologic, hydraulic, and water quality monitoring is conducted at each STA to make operational decisions, to characterize treatment efficiency, and fulfill requirements for regulatory permit reporting. Rainfall is measured with a network of gauges and also estimated from radar. Weather stations in the vicinity of each STA provide input data for the evapotranspiration estimation model. Continuous inflows and outflows are measured from automated and mostly remote controlled water control structures such as pumps, spillways, and culverts (Figs. 3, 4, 5, 6, and 7). Generally, the maximum depth of operation for the STAs is 122 cm. Target depth varies slightly cell by cell but is generally 38–46 cm deep. A large network of water stage recorders is instrumented in each STA for operational decision-making, flow computations through structures, and water depth calculations.

Water quality at the inflow and outflow structures is monitored using flow-proportional composite auto-samplers and grab samples are collected weekly. In addition to TP concentrations, many more water quality parameters are measured weekly or bi-weekly as required by permit or for performance monitoring. These parameters are alkalinity, calcium, chloride, dissolved oxygen, dissolved phosphate, hardness, magnesium, ortho phosphate, pH, potassium, sodium, specific conductance, water temperature, total Kjeldahl nitrogen, ammoniacal nitrogen, nitrate + nitrite, total suspended solids, temperature, and sulfate. Mercury and turbidity are also monitored in accordance with specific monitoring plans.

In an ongoing effort to improve performance, various levels of STA maintenance and enhancements are implemented. Short circuiting of flow due to the development of preferential flow paths limits the use of all available treatment area. Structural measures such as building internal levees, planting vegetation, and grading are implemented to improve flow distribution. Hurricanes and other extreme weather events can result in structural damage and vegetation uprooting. An STA cell that requires major rehabilitation work may need months to reach prestorm performance

Fig. 15 Cell 5 at STA-1E with flow short circuiting (*left*) and on the (*right*), after successful establishment of planted bulrush (dark green vegetation) and floating aquatic plants trapped by bulrush stands (Photos by South Florida Water Management District)

levels. Changes in vegetation require maintenance to keep the preferred type of coverage. Figure 15 depicts an STA cell where an opening in the vegetation created short circuiting (left) and was rectified by planting macrophytes to reduce short circuiting (right).

Summary

Over 18 years of operation, the Everglades STAs have demonstrated that constructed wetlands can effectively reduce TP concentrations in surface water discharges to the Everglades. An average of 73% removal efficiency is observed from all the STAs. The hydrology of the wetlands has been studied extensively and operational criteria have been continuously improving based on experience. Each STA is different due to soil type, antecedent land use, inflow rate and TP concentrations, area, cell configuration, topography, and type of vegetation cover. Therefore, constructed wetlands require tailored operations and maintenance for their specific conditions. Long-term operation of these constructed wetlands will provide data to further improve the design, operation, and treatment performance of large-scale constructed treatment wetlands.

Future Challenges

Current estimates of sediment accrual rates suggest that sediment management may be needed in the constructed wetlands after 25 or more years. The STA optimization research program continues in support of the effort to achieve further reduction of outflow TP concentrations. Understanding the factors controlling long-term performance also continues as the STAs are operated. Ongoing activities to understand and improve performance include implementation of vegetation management strategies, pre- and postrehabilitation monitoring, poststorm monitoring, and post–dry out monitoring.

Microbially Mediated Chemical Transformations in Wetlands

31

Darren S. Baldwin

Contents

Abstract

This chapter discusses how the microbiota mediate the cycling of carbon, nitrogen, phosphorus and sulfur in wetlands. Wetlands have a number of characteristics that make them hot-spots for microbially-mediated transformation of constituents. Abundant plant life, adapted to aquatic environments represents a source of carbon (energy) to fuel microbial processes. Wetlands are sites of deposition of sediments, and often interact with ground-water, both of which are source of electron-acceptors for microbial processing. Biofilms growing on emergent and submerged plants, as well the root zone of aquatic plants, are active sites of reactions that require both oxic and anoxic zones such as coupled nitrification-denitrification. Finally, many wetlands are ephemeral, meaning the sediments undergo periodic wetting and drying, which can strongly influence nutrient cycling.

Introduction

The microbiota, particularly bacteria and fungi, play a major role in the biogeochemical cycling of materials. Thus, these microbes are responsible for the degradation of organic matter and the cycling of nutrients and are crucial controllers of plant productivity and environmental resilience of ecosystems to disturbance. In short, microbial processes are critical for many aspects of ecosystem structure and function. Although wetlands represent only a small proportion (2–6%) of the Earth's land surface, they play a disproportionally large role in the cycling and transformation of chemical constituents on a global scale (Kayranli et al. 2010). The combination of soil saturation and specifically adapted plant species in wetlands is one of the main reasons that wetlands are important hotspots for chemical transformations.

The abundant plant life often associated with wetlands leads to a large input of organic carbon to the sediments when the plants die, and the fate of this material regulates the nature of chemical transformations in wetlands. This organic carbon is decomposed by microorganisms. During decomposition of the plant material, the bacteria also consume oxygen. Oxygen is poorly soluble in water – at 20 °C water that is fully saturated contains only about nine parts per million of oxygen. Because the soils usually are saturated with water, oxygen can be rapidly depleted so that environments ultimately may become anaerobic (i.e., contain no oxygen). Anaerobic zones are common in wetlands, particularly in the sediment profile. However, the loss of oxygen does not mean that life cannot occur in wetlands. There are a multitude of bacteria that can use other chemical compounds for respiration in the same way that we use oxygen. Nitrogen, carbon, and sulfur compounds as well as metals such as iron and manganese can all be used by various microorganisms in anaerobic respiration. During anaerobic respiration these compounds (known as electron acceptors) undergo reduction (gain electrons), while an organic carbon molecule is oxidized (loses electrons). Although reduction reactions are important in the cycling of many elements (including C, N, P, Fe, and S), the anaerobic zones, where these reactions can occur, are not common in the terrestrial landscape, hence the disproportionate importance of wetlands in the cycling of these elements.

Wetlands often have a number of other unique characteristics that make them hotspots for microbially mediated chemical transformations (sensu McClain et al. 2003):

Sites of sediment deposition: Wetlands are often found at the terminus of a flow pathway. Consequently, wetlands are characterized by generally having low flows relative to the watercourses that feed them. As such, terminal wetlands act as zones where fine suspended materials (including suspended sediments and particulate organic matter) are deposited, a process enhanced by the presence of aquatic vegetation such as emergent reeds, which slow the velocity of water. Therefore, the bed sediments of wetlands are often very fine and rich in organic matter. This combination of reduced flow, lack of sediment porosity, and high organic matter load results in sediments that tend to be devoid of oxygen.

Interception of groundwater: It is not uncommon for wetlands found in low areas of the landscape to intercept shallow groundwater. Groundwater can be a significant source of some electron acceptors (e.g., sulfate and nitrate) for a wetland (Baldwin and Fraser 2009). Groundwater often flows within its aquifer. Groundwater flow can be an important pathway for the export of dissolved material from a wetland.

Biofilms growing on aquatic macrophytes: Biofilms are complex assemblages of algae and bacteria that form on solid substratum and are often important sites for chemical transformations, particularly in aquatic ecosystems. One characteristic of wetlands is the presence of plant species that are adapted to partial or complete inundation for long periods of time. Substantial quantities of biofilms can form in wetlands on the submerged stems and leaves of these macrophytes.

The rhizosphere: The rhizosphere is the area immediately adjacent to the roots of plants. Although wetland sediments tend to be anoxic, wetlands support a variety of submerged and emergent macrophytes whose root systems extend into the anoxic muds. To survive, these root systems require a supply of oxygen. Many wetland macrophytes have evolved both active and passive mechanisms to transport oxygen to their root systems (e.g., Sorrell 2004). Oxygen leaking from the roots creates a zone of oxic sediment close to the root surface. Therefore, the sediment under stands of macrophytes will have zones of oxidized sediment threading through the predominantly anoxic sediment. The juxtaposition of aerobic and anaerobic zones favors a number of reactions that require a supply of an oxidized component to the anaerobic zone, e.g., coupled nitrification–denitrification (see under section "Nitrogen Cycling"). Bioavailable carbon compounds are also exuded from aquatic macrophyte roots, enhancing microbial activity in the sediment.

Wetting and drying: Many wetlands are ephemeral – undergoing periodic drying. The impact of drying on chemical transformation in wetlands is quite complex (Baldwin and Mitchell 2000). One important process is the Birch effect – named after the soil scientist H.F. Birch who first observed the phenomenon in African soils. When soils and sediments that have been dried out are rewetted, there is a pulse of nutrients (particularly C and N) released into the overlying water column. Most likely, these nutrients were previously locked up in microbial biomass, so that nutrients are released after the sediments dry.

Chemical Transformations in Wetlands

The following section discusses in more detail some of the more important microbially mediated biogeochemical cycles within wetlands. Although each cycle is dealt with separately, the cycles are not independent, and processes that occur in one cycle may impact on the cycling of another element, e.g., the anaerobic oxidation of methane during sulfate reduction.

Carbon Cycling

Carbon decomposition, either through respiration or fermentation, is the principal source of energy for non-photosynthetic organisms. Hence understanding the cycling of carbon is important in understanding ecosystem functioning. Somewhat paradoxically, wetlands are both hotspots for carbon decomposition (including the production of the greenhouse gases methane and carbon dioxide) and, simultaneously, one of the most important ecosystem types for carbon sequestration in the landscape. While wetlands only occupy a small proportion of the world's land surface area, they produce about 80% of all methane produced from natural sources (Anderson et al. 2010) yet also contain about one third of the organic matter stored in the world's soils (Kayranli et al. 2010). Much of the carbon found in wetlands is originally derived from aquatic and riparian plant material. As this material decomposes, carbon is respired as carbon dioxide or methane, incorporated into new biomass, and/or sequestered in wetland sediments. The fate of carbon will depend ultimately on the chemical structure of the carbon and the organisms responsible for its decomposition.

Most of the carbon found in plant material is incorporated into large, sometimes complex, molecules including cellulose, hemicelluloses, and lignin. Before these large molecules can be used in fermentation or respiration, they first must be broken down into smaller molecules.

Cellulose and hemicelluloses are important structural polymers made up of repeating sugar units. In cellulose, there is only one type of sugar present (glucose), while hemicelluloses may contain a number of different types of sugars. Hemicellulose can account for up to 50% of plant biomass. The actual chemical process responsible for the breakdown of cellulose and hemicellulose into their component sugars is called hydrolysis, which is the chemical breakdown of a molecule by water. However, cellulose is not very soluble in water. In nature, these polymers are broken down into their component sugars with the help of enzymes excreted by a variety of microorganisms, including fungi, as well as both aerobic and anaerobic bacteria. Therefore, cellulose degradation will occur in both anaerobic and aerobic zones, as long as there is free water available. Hence cellulose degradation will occur more rapidly in moist to wet environments such as those found in wetlands.

The other major structural polymer found in plant material is lignin. Lignin is a relatively complex molecule containing phenolic linkages (Fig. 1). Lignin is broken down principally by a group of enzymes known as phenol oxidases. These enzymes are mostly produced by fungi, rather than bacteria, under aerobic conditions (Krauss et al. 2011). Under waterlogged, and therefore mostly anaerobic, conditions often found in wetland sediment, lignin is very slow to decompose. In fact, lignin often reacts with other chemical compounds to form even more poorly soluble and unreactive molecules – a process known as humification. Humification is a process that stabilizes organic carbon molecules and is the process by which wetlands are able to sequester carbon and other nutrients (Pant and Reddy 2001).

Smaller molecules can be further decomposed by the process known as fermentation. During fermentation sugars, peptides, and amino acids are converted to alcohols and low-molecular-weight volatile fatty acids like acetate, as well as

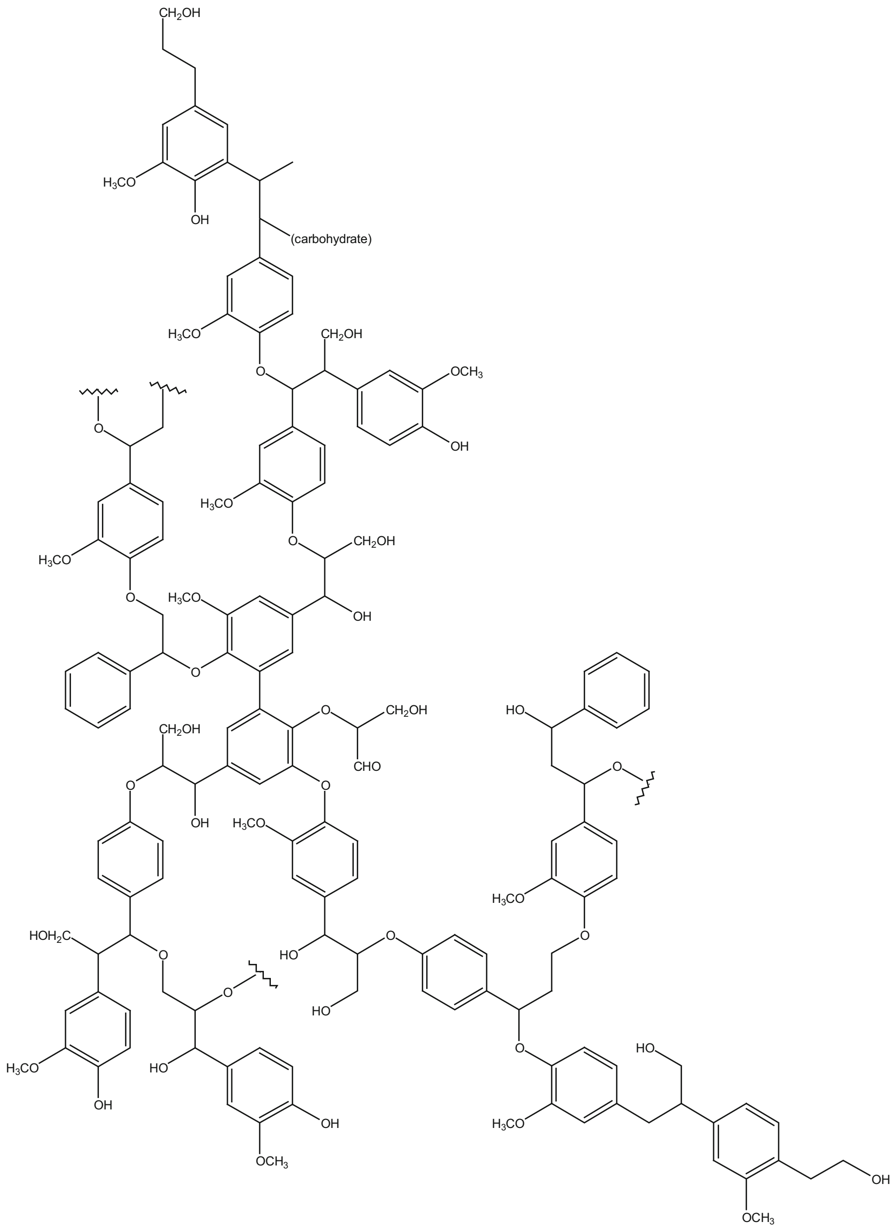

Fig. 1 Partial chemical structure of lignin

producing CO_2, hydrogen, and ammonia (NH_3). The activity of the fermenters provides important precursors to the other functional groups of anaerobic bacteria. As such, fermenters are essential anaerobic nutrient cyclers but may be limited in some environments.

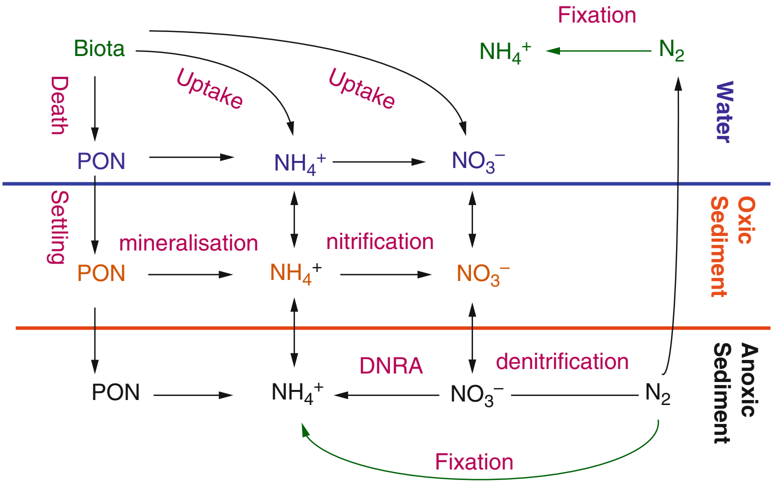

Fig. 2 Stylized nitrogen cycle (Modified after Rysgaard et al. 1993)

The terminal step in organic matter degradation in wetlands is the production of methane (methanogenesis). Methane is a potent greenhouse gas, which is produced solely under anaerobic conditions by bacteria called methanogens. Methanogens can only use a small suite of carbon molecules to produce methane (Oremland 1988), which include carbon dioxide in conjunction with hydrogen gas, formate, acetate, methanol, methylamine, or dimethyl sulfide. Most of these molecules are produced through fermentation. Not all the methane produced in a wetland is lost to the atmosphere. Under aerobic conditions, one group of methane-oxidizing bacteria, called methanotrophs, use methane as their sole source of both energy and carbon by converting methane and oxygen to form formaldehyde. Methane oxidation can also occur anaerobically, at least in marine systems (Valentine and Reeburgh 2008). Under anaerobic conditions a large group of bacteria reduce sulfate to sulfide and in the process convert methane to bicarbonate ion. There is some evidence to suggest that anaerobic methane oxidation can also occur in freshwater wetlands under the right conditions (Baldwin and Mitchell 2012).

Nitrogen Cycling

A stylized version of the aquatic N cycle is presented in Fig. 2 (after Rysgaard et al. 1993). Nitrogen can enter an aquatic system through a number of pathways including as part of either living or dead biomass (“organic N”), through fixation of N_2 gas, from anthropogenic inputs including point-source and non-point-source pollution, from aerial deposition, and groundwater sources.

After N enters the aquatic system, the N can undergo a number of transformations. Like most aquatic biogeochemical cycles, the cycling of N is predominantly mediated by the microbiota. Furthermore, similar to other biochemical cycles, different reactions occur under aerobic and anaerobic conditions. In the aerobic zone, ammonia, which is produced through the mineralization of organic N, can be converted to nitrate (via nitrite) by bacterial action, i.e., nitrification. Ammonia can also either be taken up by bacteria, algae, and/or macrophytes or, if the pH is sufficiently high, lost to the atmosphere through volatilization. In the anoxic part of the sediment, nitrate can either be reduced to ammonia (dissimilatory nitrate reduction to ammonia; DNRA) or converted to nitrogen gas (denitrification). DNRA preserves N in the system. Because N_2 gas has a low solubility in water, denitrification is a pathway for the removal of nitrogen from aquatic systems. This low solubility is particularly important if nitrification and denitrification are coupled (i.e., the two processes occur spatially close to each other), as the nitrate produced in nitrification can be quickly converted to nitrogen gas rather than being assimilated into biomass. Coupled nitrification–denitrification has to occur at the boundary of oxic and anoxic environments, and indeed the rhizosphere is believed to be the most important sites for denitrification at a global scale.

Phosphorus Cycle

Phosphorus is often the limiting nutrient in aquatic ecosystems. Excessive levels of P can lead to the formation of nuisance algal blooms and is associated with poor water quality. Like N, both natural and constructed wetlands have been used to control P concentrations before it can enter receiving waters. However, unlike N, P does not have an important gaseous form which means that any P trapped within a wetland needs to be actively harvested before it can be remobilized.

Phosphorus can enter a wetland either in dissolved form or in association with organic or mineral particles. The fraction of phosphorus delivered in each of these forms depends on the geology land use, land cover, hydrology, and the nature of the drainage network flowing into the wetland. Within a wetland, the P can be partitioned between the water column, biota, and sediments, and P can rapidly cycle between these pools.

Phosphorus in the water column can either be dissolved or particulate. Dissolved P forms include the free orthophosphate ion (HPO_4^{2-}), as polymers of phosphate molecules (“polyphosphates” such as tripolyphosphate, a compound found in detergents – $H_5P_3O_{10}$), or as part of an organic phosphorus molecule such as DNA. Only the free orthophosphate ion can be directly taken up by most bacteria, algae, and plants. Therefore to be bioavailable, the form the P is in must be converted to orthophosphate. Both dissolved polymeric phosphates and organic phosphate molecules can be converted to orthophosphate by enzymes secreted by bacteria and algae. Particulate P in the water column can either be mineral based or biotic (e.g., in bacteria and algae). Orthophosphate has a strong affinity for a number of metals including iron, calcium, and aluminum and will preferentially bind to suspended particles containing these materials.

By far the largest pool of P in most wetlands is in the sediments. P can enter the sediment through settling of particulate matter, death, and deposition of both plants

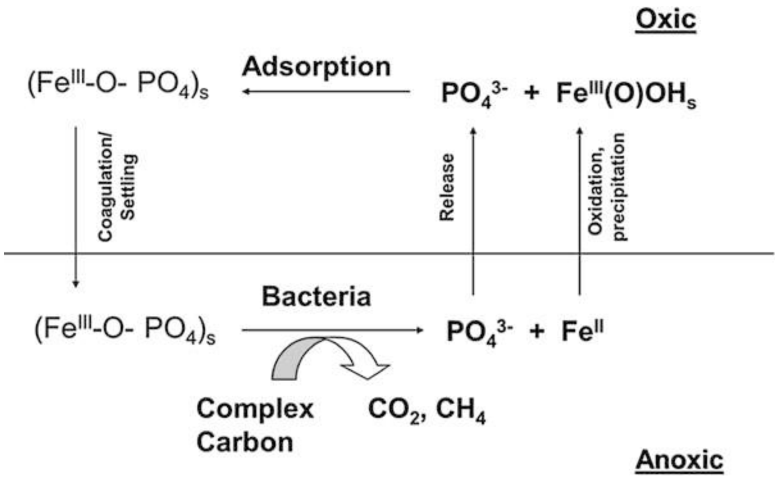

Fig. 3 Stylized phosphorus cycle

and animals and through adsorption of dissolved P onto sediment particles. While sediments may represent the largest sink in aquatic systems, these sediments may also represent a major source of P. Remobilization of P from sediments to the overlying water involves two processes, release of P from sediment particles to the interstitial waters within the sediment and transfer of P from the interstitial water to the overlying water column (Fig. 3). Although there are a number of ways that P can be remobilized from sediments into the surrounding pore water, the most important pathway seems to be the reductive dissolution of iron minerals under anaerobic conditions and subsequent release of any P adsorbed to the iron particle. Reductive dissolution can occur either directly or indirectly by bacteria. Iron-reducing bacteria directly convert oxidized (ferric) iron particles to dissolved reduced (ferrous) iron solubilizing any P associated with the particulate iron. Alternatively, there is another group of anaerobic bacteria – sulfate-reducing bacteria, which use sulfate as their electron acceptor. The sulfate is reduced to sulfide (S_2^-). Sulfide reacts with iron minerals releasing any P bound to the mineral. Under highly reducing conditions, anaerobic bacteria can reduce phosphate to phosphine, a colorless, odorless gas, which is spontaneously flammable in air. While phosphine has been detected in wetlands, the flux from the sediment is relatively small compared to the flux of phosphate.

For the P to remobilize from the pore water to the overlying water column, it must move from the sediment either by diffusion or by disturbance of the pore water in the sediment. Diffusion is a slow process and consequently probably is not important in the exchange of P from sediment pore water to the overlying water column. The disturbance may be caused by high-flow events which result in sediment bed scouring, anthropogenic causes (e.g., dredging), ebullition of gases (such as methane and CO_2) from the sediment-entraining pore water, disturbance of sediments by bottom-feeding organisms (e.g., carp), or by bio-irrigation caused by sediment-dwelling invertebrates. Alternatively, P in the sediment pore water can be taken up by aquatic plants through their root systems.

Sulfur Cycling

Traditionally, it has been assumed that the biogeochemical cycling of sulfur was only important for wetlands that were influenced by seawater. The levels of sulfur in most inland wetlands were believed to be too low to be important compared to other processes. However, mostly through the action of humans, the concentration of sulfur in many inland wetlands worldwide has increased substantially over the last few decades (e.g., Jansen and Roelofs 1996). There are a number of sources of sulfur to wetlands. Burning of sulfur-rich fossil fuels led to substantial aerial deposition of sulfur in the northern hemisphere (acid rain). While there are now actions in place to mitigate this pathway, the legacy of high concentrations of sulfur remains. Increased sulfur has also been associated with the salinization of wetlands. Salt of marine origin contains sulfate; hence where there are high levels of salt in the landscape, we also find significant concentrations of sulfate. Altered hydrology in landscapes (as a result of land clearing, irrigation, and drainage networks) has resulted in increased mobilization and discharge of saline groundwater in the landscape with associated increased mobility of sulfate and accumulation in wetlands (Baldwin and Fraser 2009). Sulfur compounds are also found in agricultural fertilizers and soil ameliorants. Elevated levels of sulfate are also associated with the discharge of municipal wastewater partially through the use of aluminum sulfate as a flocculent in water treatment plants.

The dominant form of dissolved sulfur under aerobic conditions is sulfate. Sulfate is the terminal electron acceptor for a group of anaerobic bacteria called sulfate reducers. Sulfate-reducing bacteria (SRB) can use a wide range of organic substrates including low-molecular-weight organic acids, aromatics, hydrocarbons, amino acids, and ethyl alcohol for the dissimilatory reduction of sulfate to produce sulfide. Metabolic by-products of SRB include carbon dioxide, hydrogen gas, and acetate, each of which is substrates for further anaerobic bacterial processes including sulfate reduction. The sulfate-reducing bacteria can outcompete methanogens for carbon substrate so that sulfate reduction will suppress methane production in wetlands. Sulfate reduction has also been implicated in anaerobic oxidation of methane to carbon dioxide in wetland sediments, further reducing methane emissions. Sulfate reduction has also been linked to the conversion of mercury to methylmercury in wetland sediments. Methylmercury is a potent neurotoxin and endocrine-disrupting chemical that can bioaccumulate through the food web.

The sulfide produced into during sulfate reduction can be oxidized to either elemental sulfur or sulfate by a range of anaerobic photosynthetic bacteria or aerobic lithotrophic bacteria, respectively. A lithotroph is a bacterium that can use a reduced inorganic substrate for biosynthesis. Alternatively sulfide can react with metal containing minerals to produce metal sulfides. The most common metal sulfides found in wetlands are iron sulfides including mackinawite (FeS), greigite (Fe_3S_4),

Fig. 4 Bottle Bend Lagoon, Murray River Watershed, Southeastern Australia (© Murray-Darling Freshwater Research Centre used with permission)

and pyrite (FeS_2). If the metal sulfides are exposed to oxygen (e.g., because of a drying out of the wetland), these compounds undergo a complex series of reactions that ultimately produces acid. If the amount of acid produced is greater than the system's ability to neutralize that acid, then the wetland can acidify. One of the most dramatic examples of this is Bottle Bend Lagoon, an oxbow lake near the Murray River in Southeastern Australia (Fig. 4). A partial drying event exposed metal sulfides to the atmosphere. The pH in the wetland fell from about eight to less than three in a matter of weeks and remained highly acidic for many years until the acid was flushed from the wetland during a large overbank flood (McCarthy et al. 2006). Acidification can also mobilize metals from the sediment.

Future Challenges

Wetlands play a critical role in the global biogeochemical cycling of a number of important elements including carbon, nitrogen, phosphorus, and sulfur. However, across the globe a large number of wetlands have been permanently altered because of human activity. Into the future, the combination of climate change and increasing human population will put further pressure on remaining wetlands. Loss of individual wetlands occurs at a local scale, but cumulatively the effects are global in nature.

Our challenge into the future is to balance the needs of local communities without further disrupting the important role wetlands play in the cycling of important constituents.

Carbon Flux from Wetlands

32

Hojeong Kang and Inyoung Jang

Contents

Abstract

Human activities have accelerated decomposition in wetland ecosystems, destabilizing carbon stocks in them. In particular, global climate change, drainage and atmospheric deposition are key activities that affect wetland carbon cycle substantially. Global climate change can affect carbon decomposition in wetlands

by warming effects as well as more frequent droughts. Elevated CO_2 itself can increase dissolved organic carbon leaching from wetlands through enhanced primary production. For coastal wetlands, sea level rise can also affect carbon mineralization by changes in water chemistry as well as oxygen availability. Wetlands have been subject to drainage for the development of agricultural fields and urban dwellings which can accelerate carbon decomposition by aeration. Finally, nitrogen and sulfur deposition can either increase or inhibit carbon decomposition depending on the nutrient status and locations. Overall, human activities can accelerate carbon decomposition in wetlands resulting in greater carbon releases into the atmosphere as CO2 or CH4, and into the aquatic ecosystems as DOC.

Introduction

Wetlands contribute to the global carbon cycle via two basic processes. One is primary production, which takes carbon dioxide from the atmosphere and converts it to organic carbon, comprising plant biomass and soil organic carbon. The second is the decomposition of organic matter, which releases carbon gases to the atmosphere. They also have several unique characteristics through which they have a significant effect on the global carbon cycle. For example, although northern peatlands have a low rate of primary production, their decomposition rate is even lower, resulting in the accumulation of undecomposed materials as peat. In contrast, some salt marshes exhibit very high primary production, higher than that of tropical forests. Each of these processes is discussed below.

Primary Production in Wetlands

In wetlands, primary producers, such as trees, shrubs, and floating plants, fix atmospheric carbon dioxide via photosynthesis. Because carbon dioxide is rarely a limiting factor, nutrients (e.g., nitrogen and phosphorus), water-logging, light intensity, and temperature often control the overall primary production of wetlands. The amount of carbon fixed by global wetlands is estimated to be 137 Tg year^{-1} (Mitra et al. 2005). As the types of wetlands are extremely diverse, their primary production is also highly variable. For example, many northern peatlands, such as bogs, are dominated by *Sphagnum* mosses, which usually grow in nutrient-poor and relatively cold regions. Therefore, their primary production is small. In contrast, marshes, another wetland type often found in temperate regions, have a much higher level of primary production (Mitsch and Gosselink 2007). Given this large variability, primary production in four widespread wetland types is discussed separately.

Peatlands

Peatlands are mainly found in high-latitude areas (northern peatlands) but also in tropical regions (tropical peatlands) or high-altitude areas of temperate regions (mountain peatlands). A typical peatland is a Sphagnum-dominated "bog," where the main input of water is from rain with low levels of cations and nutrients. These systems are referred to as "ombrotrophic." The primary production of such system is generally lower than that of other wetlands, ranging from 250 to 500 g C m^{-2} $year^{-1}$ (Mitsch and Gosselink 2007). In contrast, peatlands also include "fens," which are often influenced by the inflow of water from an adjacent watershed or ground water (called "lithotrophic"). This results in a higher primary production than that of bogs (Mitsch and Gosselink 2007).

Freshwater Marshes

Marshes can be found in temperate and tropical regions. The most distinctive difference between marshes and peatlands is that most marshes are dominated by mineral soils. Marshes are often characterized by emergent, submerged and floating-leaved plants. Depending on the annual mean temperature, hydrological patterns, and nutrient availability, the primary production of marshes ranges from 650 to 1600 g C m^{-2} $year^{-1}$ (Bridgham et al. 2006).

Salt Marshes

Salt marshes normally occur close to the oceans and are dominated by plants with special adaptations to high salt concentrations. For example, *Spartina* and *Salicornia* (glasswort) species are typically found in salt marshes in temperature regions. Although high salinity can stress most plants, specialized plants in salt marshes can also obtain energy from tidal flow and nutrients from adjacent seawater and freshwater. As a result, the primary production in salt marshes is often greater than that of other types of ecosystems, not only other wetlands. For example, the average primary production of salt marshes is estimated to be 900–2000 g C m^{-2} $year^{-1}$ (White et al. 1978).

Swamps

This type of wetland is dominated by large trees. A large amount of carbon occurs as standing biomass in this ecosystem, and primary production ranges from 500 to 1800 g C m^{-2} $year^{-1}$ (Titlyanova 2008).

Decomposition in Wetlands

Organic matter can be supplied to wetlands by primary production on site as litter and root exudates or by delivery from inflow water. Organic matter can accumulate in wetlands or is decomposed by invertebrates or microorganisms. In particular, various types of microorganisms, such as bacteria, fungi, and prokaryotic microbes (*Archaea*), play a central role in the complete decomposition of organic matter. The decomposition of organic matter in wetlands is of great importance because it regenerates inorganic nutrients for plant growth, produces various gases, provides dissolved organic carbon to wetland water, and determines whether wetlands accumulate carbon or not (Mitsch and Gosselink 2007).

Decomposition rates in wetlands are determined by several factors, including the chemical properties of organic matter (recalcitrant versus labile), oxygen supply (aerobic versus anaerobic), temperature, nutrient supply (eutrophic versus oligotrophic), and microbial properties (Bridgham et al. 2006). For example, easily decomposable carbon, such as monomeric sugar, is promptly decomposed under high temperature and low water table conditions (i.e., high oxygen supply) and with a sufficient supply of nitrogen. In contrast, litter with a high lignin content in cold and water-logged conditions, such as in northern peatlands, is very slowly decomposed.

From a carbon-cycle perspective, the fate of organic carbon decomposed in wetlands occurs in three forms: carbon dioxide (CO_2), methane (CH_4), and dissolved organic carbon (DOC). Gas emission is often measured by analyzing gas concentrations, which can be collected in a static chamber installed on wetland surface (Fig. 1). Key

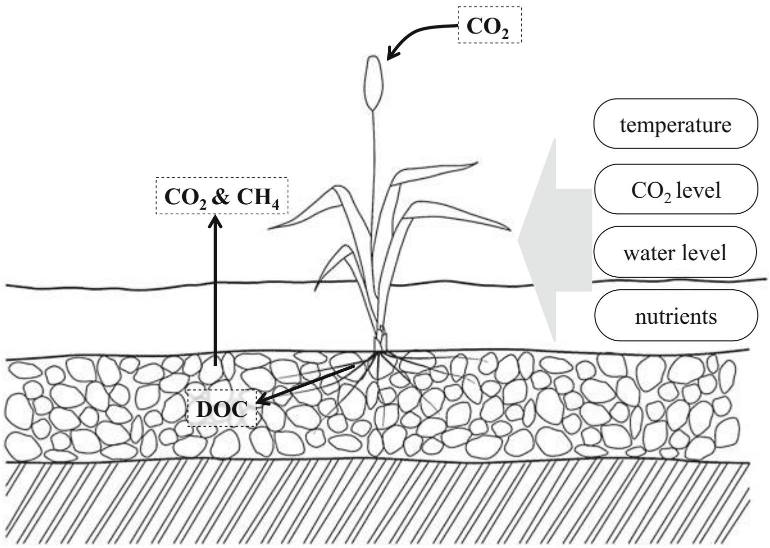

Fig. 2 Influences of environmental changes on carbon dynamics in wetlands

controlling variables for carbon cycle and decomposition are presented in Fig. 2. The pathways for the generation of these products are discussed in detail in the following sections.

Carbon Dioxide

The most common product of the microbial decomposition of organic matter is carbon dioxide. When oxygen is available, microorganisms decompose and metabolize various forms of organic carbon and release CO_2 as a final product. Wetland types differ substantially in the amount and characteristics of organic matter, and thus CO_2 emissions from wetlands widely vary. Furthermore, even within a single wetland, CO_2 release patterns often show a strong seasonality as well as a strong daily variation due to water level and temperature changes. In general, if sufficient carbon is supplied under high temperature and low water level conditions, CO_2 emissions peak. The total amount of CO_2 released from global wetland soils is estimated to be 76.5 Pg C year^{-1}, although substantial uncertainties are involved (Mitsch and Gosselink 2007).

Methane

Methane is mainly produced by a certain type of *Archaea*, collectively referred to as "methanogens" (Aselmann and Crutzen 1989). In wetlands, a lack of oxygen activates fermentation processes that generate products, including various organic acids (e.g., acetate) and hydrogen. Methanogens can metabolize such organic acids,

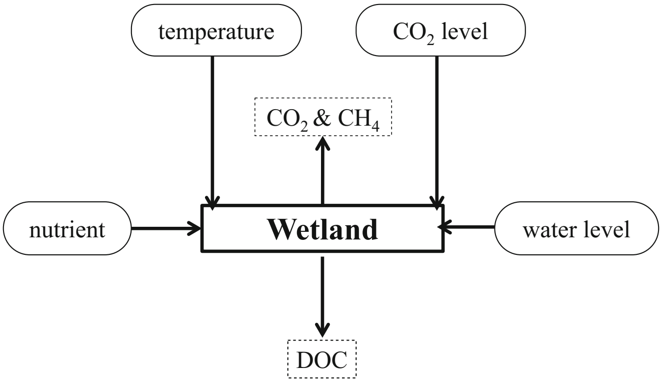

Fig. 3 Biochemical pathway of CH_4 oxidation to CO_2 by methanotrophic bacteria

hydrogen, and other compounds to produce CH_4 as the final product. This process can occur under extremely reduced conditions only with an ample supply of organic carbon, which is one of the typical conditions of many wetlands (Fig. 3). Accordingly wetlands represent the greatest source for CH_4 globally, contributing 50% of the total emission from natural sources, including rice paddies (Aselmann and Crutzen 1989). Another important microbial process is CH_4 oxidation (Mitsch and Gosselink 2007). A specific type of bacteria named "methanotrophic bacteria" can oxidize CH_4 to acquire energy under aerobic conditions. Methane produced in deeper parts of wetlands is released near the surface where it can be converted to CO_2 by methanotrophic bacteria. In most wetlands, methane can be emitted via bubbles (called 'ebullition'), diffusion through water, and flux through vegetation.

Wetland plants also play a key role in CH_4 production and emission from wetlands (Mitsch and Gosselink 2007). First, they provide organic carbon needed for CH_4 production as litter or root exudates. Second, plant roots release oxygen into wetland sediments, which can inhibit methanogenesis. Last, plants can function as a conduit for CH_4 release and thus facilitate the release of CH_4 produced from wetland sediment into the atmosphere.

Dissolved Organic Carbon

DOC is operationally defined as any organic carbon material in water that can pass through a 0.45 μm filter. Due to its small size, DOC often represents carbon that is easily degraded by microorganisms, although it can also be composed of highly recalcitrant carbon, such as phenolics found in peatlands. DOC is important for several reasons: (1) it is an important component of organic energy pathways in ecosystems; (2) it absorbs various materials, including organic pollutants and heavy metals to increase their mobility; (3) the flux of DOC is acknowledged as an important component of the global carbon cycle.

Abstract

Wetlands are important and essential components of landscapes because they provide important goods and services to societies. In some instances wetland values are difficult to quantify (e.g., aesthetic and recreational values) while other services that can be quantified (e.g., retention of water to mitigate flood events, recharge of groundwater, carbon storage, removal of pollutants and toxics); even though methods for quantification may not be fully developed. Three ecological processes (primary production, secondary production, decomposition) are key elements in enabling wetlands to support earth's life support systems that provide the global services that benefit humankind as well as directly generating food, fuel, and raw materials that support human needs. While the functional benefits that wetlands provide are widely known and accepted, there remain many challenges to integrating scientific knowledge about wetlands into societal decisions that restore or secure the ecological integrity of wetlands to assure that they continue to freely provide essential goods and services.

Primary production · Secondary production · Decomposition · Nitrogen · Phosphorus · Goods and services

Introduction

For decades it has been widely recognized that ecological processes that occur in wetlands (e.g., primary and secondary production, decomposition) result in important functions as well as goods and services from which societies benefit greatly. The benefits that wetlands provide to society have, in fact, been the primary driving force behind many efforts to conserve and restore wetlands (e.g., Maltby and Marker 2009), including international efforts such as the Ramsar Convention on Wetlands of International Importance (http://www.ramsar.org/cda/en/ramsar-home/main/ramsar/1_4000_0__) and the inclusion of wetlands such as the Sundarbans National Park in India in the list of UNESCO World Heritage Sites (http://whc.unesco.org/en/list). The Ramsar Convention now includes more than 2,160 sites covering more than 205.7 million hectares of wetlands. The fact that wetlands provide important functions at local, regional, and international scales (Larson and Mazzarese 1994) has resulted in a wide variety of efforts designed to assess the condition and restoration of wetlands (e.g., Maltby and Barker 2009) as well as provide for their protection, including geographically extensive wetlands that had been negatively impacted by human activities (e.g., Florida Everglades, Mesopotamian wetlands).

The number of functions that wetlands provide is large (e.g., de Groot 1992), but they can be organized into categories that can be used to direct attention to the ecological processes that are important determinants of the structure and function of wetlands. Keddy (2000), for example, organized the functions described by De Groot into four categories as follows:

- **Regulation functions** which include the ecological processes that enable wetlands to, in part, provide the Earth's life support systems (e.g., regulate carbon dioxide and oxygen in the atmosphere, regulate the flow and storage of water in catchments, store and recycle human wastes)
- **Carrier functions** which provide space and substrates for services such as nature protection, cultivation of wetland-dependent crops, and the location of settlements such as the long history of human occupation of wetlands associated with the Tigris and Euphrates rivers (Heyvaert and Baeteman 2008)
- **Production functions** such as the generation of food, fuel, and raw materials for human uses
- **Information functions** such as spirituality, heritage, and scientific research

The ecological processes described here are responsible for functions in all four categories, but they are key elements of the **regulation** and **production** categories identified by Keddy. They are primary production, secondary production, and decomposition.

Primary and Secondary Production

The capture of solar energy through the process of photosynthesis is the basis for almost all ecological functions on Earth, including many of the goods and services that are provided by wetlands. Primary production has two components: gross primary production (GPP) and net primary production (NPP). NPP is the most commonly cited measure of primary production because the simplest way to measure production of wetland plants is to harvest and weigh the vegetation in wetlands dominated by herbaceous species or by measuring trees in wetlands dominated by woody species to estimate biomass (Whittaker and Marks 1975). In wetlands dominated by herbaceous or woody species, direct measurements or estimates of biomass is the metric that is used as a measure of NPP.

Primary productivity of wetlands, both GPP and NPP, varies widely depending on a variety of factors, but it has been documented on numerous occasions that wetlands are among the most productive ecosystems on Earth, usually benefitting from an adequate supply of nutrients and water. A compilation of productivity data in which wetlands are compared with other ecosystems has been provided by Cook et al. (2009). The table provides a broad summer of patterns of wetland productivity across climate zones. For each type of wetland listed in the table (bogs, fens, swamps, marshes, floodplains), productivity on a yearly basis decreases from the tropics toward to poles, ranging from a high NPP of 1,500–4,000 g m^2 $year^{-1}$ for marshes in the tropics to 100–300 g m^2 $year^{-1}$ for bogs and fens in the polar region. This pattern is consistent with the notion that GPP and NPP are higher in warmer climates but the rates are highly variable from one geographic location to another and they depend on the availability of resources that are required to support photosynthesis. Annual rates of primary production, while informative for comparative purposes, can also be somewhat misleading because wetlands that have low annual production can be highly productive on a daily basis. Wetlands in arctic and alpine habitats can have, for example, daily rates of production that are very high due to warmer temperatures and almost continuous light in the summer growing season.

Examples of publications that have focused on wetland primary production can be found in review articles (e.g., Whigham et al. 1978; Hopkinson et al. 1980; Nixon 1980) and books (e.g., Lieth and Whittaker 1975; Lieth 1978). Typically estimates of NPP are lower than the actual NPP because few investigators have measured how much of the NPP was allocated to belowground biomass. It follows that because most of the biomass in the majority of wetland plant species occurs belowground (Whigham and Simpson 1978; Darby and Turner 2008), that actual NPP should be higher than the values reported in the examples cited. Belowground production is, however, very hard to measure because of the difficulty in determining how much of the biomass accumulated during a single growing season compared to the total amount of biomass that is present. As a result, there have been very few estimates of belowground biomass production in perennial wetland plants compared to many more studies that describe the distribution of belowground biomass. Two examples of wetland annual plant species (Whigham and Simpson 1977; Sickels and Simpsons 1985) suffice to demonstrate that the amount of NPP allocated to belowground biomass is significant. Wild rice (*Zizania aquatica* var. *aquatic*) and giant ragweed (*Ambrosia trifida*) are both annual species that occur in tidal freshwater wetlands, one of the most productive types of wetlands in the world (Whigham 2009). Using annual species to demonstrate the relationship between above- and belowground biomass production is useful because all of the belowground biomass in annual species is formed in the same growing season as the aboveground biomass. In the two examples of annual species, wild rice NPP was estimated to be 1,453 g m^2 $year^{-1}$, and about 1/3 was root biomass. Giant ragweed NPP, in the same wetland in which wild rice was studied, was even higher (6,574 g m^2 $year^{-1}$) with root biomass equal to almost half (1,500 g m^2 $year^{-1}$ for roots vs. 3,265 g m^2 $year^{-1}$ for shoots) of the annual production.

Secondary production is a measure of how much NPP is consumed directly or indirectly by animals and turned into biomass of animals, microbes, etc. In the vast majority of wetlands, only a relatively small percentage, a universal average estimate is 10%, of the NPP is consumed directly by animals, and the remainder enters the food webs associated with decomposition, the process described in the next section. There are examples, however, of the importance of NPP produced by wetland plants to animal species and communities, both negative and positive.

The migration of vast numbers of waterfowl and within-region migration of ungulate herds to arctic and tropical wetlands is associated with wetland production. Primary production of arctic wetland is low on an annual basis, but during the summers with 24-h daylight, the rates of NPP are equal to those of the most productive wetlands. As a result, large amounts of NPP in arctic wetlands are consumed by migratory animals such as greater snow geese (Masse et al. 2001; Jefferies et al. 2009). In tropical environments, the seasonal movement of animals into wetlands to consume NPP during the dry season is critically important (Keddy 2000; Keddy et al. 2009).

Examples of negative impacts on primary production associated with animals are almost always related to changes in the behavior of animals or the consequences of human activities (Jefferies et al. 2009). In tidal freshwater wetlands, wild rice (see above example of wild rice NPP) is an important species as the seeds provide an important resource for migratory birds and mammals. In recent decades, however, populations of Canada geese stopped migrating and established large populations along the Patuxent River (Maryland, USA). The nonmigrating geese had a negative impact on wild rice populations by consuming seedlings in the spring during the period when the adult birds are molting and juvenile birds are too young to fly. Eventually the decline in wild rice reached a point where there was concern that the species would no longer be viable. As a result, changes in goose-management practices resulted in a reduction of the population of nonmigrating geese and subsequent recovery of wild rice populations (Haramis and Kearns 2007).

A similar situation has happened in Europe where changes in land-use practices have resulted in dramatic increases in waterfowl populations, especially geese and swans, resulting in increased damage to vegetation on wintering habitats as well as breeding habitats in the summer arctic breeding ground (Jefferies et al. 2009).

Decomposition

Following senescence, most wetland NPP enters the detritus pool where decomposition results in its conversion to carbon dioxide and other carbon-containing compounds that may be metabolized or become part of the long-term storage of recalcitrant carbon compounds (i.e., hemicelluloses and lignin) that are associated with wetlands. Importantly, decomposing wetland plant biomass contains the nutrients and energy that support a wide range of complex aerobic and anaerobic decomposition-related processes (Megonigal et al. 2004). The decomposition process also is a key component, directly or indirectly, of the primary production process as well as the biological, chemical, and physical processes responsible for the goods and services provided by wetlands.

The fate of the senesced NPP in wetlands depends on many factors such as the presence, absence, or concentration of oxygen in the substrate, the nutrient and oxygen content of water that enters the wetland, the temperature, and the nutrient status of the plant material (Brinson et al. 1981; Vepraskas and Faulkner 2000; Verhoeven 2009). The nutrient status of the plant material varies widely based on the types of plants that are present, but generally, decomposition proceeds faster in wetland dominated by herbaceous species compared to wetland dominated by trees and shrubs (Webster and Benfield 1986). Verhoeven (2009) described four categories of plant materials that enter the decomposer food web: (1) easily degraded materials which disappear in weeks to months, (2) plant cell wall material (cellulose and hemicellulose) that decomposes of over a period of months to a year, (3) lignins and waxes which persist for several years, and (4) polyphenolics with antibiotic properties which influence the rate of decomposition of materials in the first three categories.

A general understanding of the decomposition process is that inorganic- and organic-soluble materials (category 1 above) are released by physical processes or decomposer activity soon after senescence and become available for uptake by plants and microbes, retention in the wetland substrate, or export to other ecosystems. Following the loss of the soluble labile materials, the more recalcitrant materials (categories 2 and 3 above) decompose slowly with compounds that are most resistant to decomposition (e.g., plant parts containing lignin), becoming part of the long-term storage function through microbially mediated processes (Fogel and Tuross 1999). The long-term storage of recalcitrant carbon-based compounds in wetlands is one reason behind the prevailing view that wetlands are long-term sinks for carbon and thus are an important component of efforts to reduce the impacts of climate change (Dise 2009).

The dynamics of nutrients during decomposition are closely tied to the fate of carbon as microbes use the organic material as a source of energy. The fate of nitrogen (N) and phosphorus (P) provides examples of the relationships between the characteristics of the substrate in which decomposition is occurring and the fate of essential nutrients. Both nutrients are required for plant growth, and wetland productivity is typically limited by N, P, or both (e.g., Koerselman and Meuleman 1996; Sundareshwar et al. 2003; Elser et al. 2007).

Nitrogen

The fate of nitrogen is complex, and while all components of the processes are still not fully understood (Megonigal et al. 2004; Verhoeven 2009), the conversion of N from one form to another during the processing of organic matter decomposition by microbes is intimately tied to the physiochemical characteristics of wetland substrates and results in changes in nutrient status and subsequently the services that wetlands provide. The sequence of N-related events is tied to the degree to which wetland substrates are aerobic or anaerobic and numerous processes are involved. When oxygen is present, bacteria and fungi can mineralize small carbon-containing compounds completely to carbon dioxide resulting in the production of ammonium (NH_4). Ammonium can be assimilated by plants to support primary production, or it can follow several pathways that influence water quality.

Ammonium is converted directly to nitrate by nitrification or indirectly to nitrite (NO_2) and then (NO_3) by ammonium oxidation in the presence of oxygen. The pathway from ammonium to nitrate can be reversed, but nitrate can also be converted to dinitrogen gas (N_2) by the process of denitrification. N_2 gas can also result from the oxidation of ammonium or nitrate. Denitrification is an important process in wetlands because N_2 losses to the atmosphere result in a quantitative loss of nitrogen and, potentially, an improvement in water quality. Denitrification, which is limited by the amount of nitrate and oxygen in the substrate, can occur in wetlands that are highly anaerobic because of the presence of oxygenated microzones around plant roots. In those instances, oxygen diffuses from plant roots resulting in mineralization and subsequently denitrification. The ability of wetland plants to assimilate ammonium and nitrate coupled to their ability to oxidize substrates has been successfully employed in the use of constructed wetlands to provide water quality improvement in a variety of landscape and social settings (Vymazal et al. 2009).

The conversion of nitrogen from one form to another may not always have a positive benefit. A product of denitrification is nitrous oxide (N_2O) which has been implicated in the climate change debate (Wuebbles 2009) because it has a long half-life in the atmosphere and contributes to the production of ozone in the trophosphere. Perhaps most important, it is approximately 300 times more effective than carbon dioxide as a greenhouse gas. The role of wetlands as a current and future source of atmospheric N_2O is, however, not clear because the presence of water, a common feature of wetlands, promotes the consumption of NO and N_2O by reducing their diffusion to the atmosphere and increasing residence time in the soil where they can be consumed by microorganisms.

While not a product of nitrogen cycling, another climate-related produce of decomposition is methane (CH_3). In the series of oxidation-reduction reactions that occur in wetlands, methanogenesis is the final process, occurring in substrates with a redox of less than −250 mV. In methanogenesis, bacteria use carbon dioxide as an electron acceptor, and the end product of organic matter decomposition is methane and carbon dioxide. Like N_2O, CH_3 is a strong greenhouse gas. As long as there is oxygen present in wetland soils or water, most of the methane produced in highly anaerobic microsites will be used by methane-oxidizing bacteria, and little will escape to the atmosphere. If there is no oxygen present, however, the wetland could be a source of CH_3 and thus contribute to global warming. The role that wetlands play in contributing to atmospheric CH_3 is currently an area of active research and discussion (Ortiz-Llorente and Alvarez-Cobelas 2012).

Phosphorus

Phosphorus (P) is an essential plant nutrient, and similar to N it also follows many pathways in wetlands during the decomposition process. Unlike N, however, very little P cycling involves an atmospheric component, and the one volatile compound that has been identified (phosphine) is apparently only emitted at very low levels from wetlands (Richardson and Vaithiyanathan 2009). Phosphorus is an important element in terms of the goods and services that wetlands provide because many wetlands are P limited and activities associated with human activities (e.g., discharge of sewage, erosion of soil particles that are rich in phosphorus, application of fertilizers containing P) often result in water quality problems because most wetlands have a limited ability to store phosphorus through plant uptake and physical and chemical storage in wetland substrates.

The primary sources of P for wetlands are atmospheric deposition in precipitation and input from water that enters wetlands, usually as surface water from streams or runoff from adjacent upland watersheds. Within wetlands some of the available P, typically in the form of phosphate (PO_4), is taken up by algae, microbes, and plants, while the remainder is adsorbed and exchanged on inorganic and organic particles. Usually the amount taken up actively by biota is only 10–15%, and the remainder is sequestered in soils or litter (e.g., Richardson 1985). The uptake of P in soil and litter leads to a number of studies in which wetlands were used to remove P, as well as N and other nutrients and pathogens, for water quality improvement (Kadlec 2009).

During the initial stage of decomposition, extracellular enzymes produced by microbes play an important role in assimilating as well as releasing P from labile plant material (Wetzel 1999), and microbes also play an important role in processing organic P in wetlands (Richardson and Vaithiyanathan 2009). The fate of P following its removal by biological and physical processes in wetland substrates is complex and depends on the same set of factors that are also important in the N cycle (the presence or absence of water, presence of absence of oxygen, pH), but unlike N, the transformations that occur in the P cycle are also highly dependent on the presence of elements (e.g., Al, Ca, Fe, Mg) to which P can bind tightly and subsequently enters long-term storage as peat/sediment accretion and rarely is ever again available for plant uptake. The ability of wetland substrates to provide short- or long-term storage of P is primarily dependent on the amount of Al and Fe that is present. When those two elements are in abundance, wetlands have a high absorptive capacity for P. Alkaline soils with a high Ca content (e.g., Florida everglades) also have a high absorptive capacity and provide long-term storage, but there are also limits to the amount that can be absorbed and stored when P-loading rates are high. Peat soils that are low in Al and Fe represent the other end of the absorption-storage spectrum and have low potential for both features.

Linking Wetland Primary Production and Decomposition to Ecological Services

In addition to the fate of N and P in wetlands as a result of the complex interactions that occur during decomposition, there are other elements required to support primary production. In addition to N and P, however, it is worth describing recent efforts that demonstrate that organic carbon, the primary constituent of wetland substrates (Dise 2009), also plays an important role in supporting primary production, especially in coastal ecosystems.

Carbon in wetland substrates occurs in many forms, and the export of dissolved organic and inorganic carbon from wetland results in a distinct carbon signature that affects the optical and chemical characteristics of estuarine water (Tzortziou et al. 2011). Recent efforts to characterize the role of high molecular weight carbon compounds, referred to as colored dissolved organic matter (CDOM), have indicated that it plays an important role in supporting algal production because it is highly photoreactive and more reactive than CDOM exported from upland ecosystems to estuarine waters (Tzortziou et al. 2007 and P. Neale 2014, personal communication).

Other wetland carbon-related issues are known to be important components of the goods and services provided by wetlands. The rate at which wetlands accumulate carbon and other nutrients, to a large degree is a function of the interacting effects of primary production and decomposition, has become an issue of concern related to the ability of wetland to persist when they are exposed to high levels of nutrient and sediment runoff from human activities (Maltby and Barker 2009). Another wetland-related factor that has been recognized to be important is whether or not coastal wetlands will persist as sea levels increase in response to climate change. It seems logical that some of the climatic factors responsible for sea level rise, increased temperatures in response to increased atmospheric CO_2, would benefit primary production of coastal wetland vegetation, but the ability of wetlands to keep pace with sea level rise is complicated by other factors such as sediment loads and increased eutrophication of coastal waters. All of these factors interact to determine how an individual tidal wetland will respond to sea level rise, and the primary question is whether or not the elevation of wetland substrates can keep pace with the rate of sea level rise (Langley et al. 2013). There is currently no clear answer to this question, but the answer ultimately is strongly influences by the rates of primary production of emergent plants and the rates of decomposition of the organic matter produced by the plants.

Two recent experiments shed light on the complexity of these interacting factors. The increase in the surface elevation of a Maryland brackish tidal wetland was almost twice the current rate of sea level rise when the plants were given increased levels of carbon dioxide, but when they were given nitrogen and carbon dioxide, the increase in surface elevation was equal to the rate of sea level rise. The latter result suggests that increased nitrogen resulted in higher decomposition rates, especially of belowground biomass, thus negating the positive effects of elevated carbon dioxide on net primary production. When tidal flooding (i.e., how long plants were flooded and the depth of flooding) was added as a third factor in another experiment, the results were more complicated as the responses of individual wetland species varied with one dominant species benefitting from additional nitrogen and carbon dioxide when the site flooded more frequently and to a deeper depth compared to another dominant wetland species that benefited from additional nitrogen but did not tolerate more frequent tidal inundation.

It is clear that the dominant wetland processes (primary and secondary production and decomposition) are all key components underlying the importance of wetlands from an anthropocentric viewpoint. While there is much more to be learned about each of the processes described here, our understanding of the linkage between wetland function and structure provides clear evidence of the past, current, and future importance of wetland ecosystems. Wetlands are clearly far more important to human cultures than would be indicated by the amount of land and water that they cover. Wetlands will continue to be used to improve water quality, and hopefully wetland restorations and declines in the rate of wetland losses will reduce the impacts of climate change while conserving and restoring biodiversity. Wetlands will continue to provide resources that support human societies (e.g., peat harvested for a variety of cultural purposes as well as providing a carbon-rich fuel in some parts of the world). Wetland substrates formed millennia ago will continue to be sources of fossil fuels upon which modern cultures depend. Still other plant remains that were stored in wetland substrates only later become items of cultural importance (e.g., fossilized animal bones that help understand evolution and past climate changes, human remains that are used to better understand previous cultures). For these and many other reasons not presented here, the processes that provide the goods and services that wetlands provide are key to a sustainable future.

Future Challenges

Knowledge about the structure and function of wetlands has increased enormously in the past several decades, including the public view of wetlands. Historically wetland had been viewed as wastelands that should be destroyed or converted to more appropriate uses (e.g., Stine 2008). Increasing awareness of the benefits that wetlands provide to societies has resulted in international, national, regional, and local laws directed toward the conservation and restoration of wetlands. In the USA and Canada, for example, there are national no net loss of wetland goals.

Wetlands, however, remain at risk around the world, and future challenges persist to assure that the processes that are described in this contribution continue to provide valuable wetland functions on local, regional, national, and international scales. While there are many challenges to more fully understand primary and secondary production and decomposition, it is more important to integrating knowledge about these processes into a more comprehensive assessment of the linkages between wetland processes and the goods and services that wetlands provide at all social levels. In the past, the goods and services that wetland processes are responsible for have been provided to societies at no cost, but the level of human impacts across the Earth has reached the point where the processes are threatened because of habitat loss, eutrophication, and discharge of ever-increasing numbers of contaminants into the environment. The challenges to the scientific community are to and more effectively integrate ecological understanding about natural wetland processes into societies so that economic and political decisions are made that assure the continuance of the natural processes described in this contribution.

Abstract

Several environmental factors influence plant photosynthetic process in wetlands, thus, affecting growth, productivity, and overall wetland functioning. Assessment of photosynthetic functioning is critical to the understanding of the range, threshold, and optimal conditions for plant growth in wetlands. In most wetlands, flooding is the predominant environmental factor although in certain wetlands other factors such as periodic drought, salinity, and temperature extremes may also affect plants. This paper focuses on photosynthetic responses to changes in wetland conditions following flooding events. Soil flooding leads to soil anoxia that is accompanied by production of many soil substances, known to be harmful to plants. As a result, wetland plants may suffer periodic stresses leading to physiological dysfunctions and reduced photosynthesis. The contribution of these soil compounds to the overall photosynthetic reductions, as well as plant response mechanisms involved are discussed. Also, additional key references on the topic are provided.

Introduction

Assessment of plant carbon fixation in response to environmental factors in wetlands is fundamental to the understanding of wetland primary productivity, development, and function. Plant growth depends on photosynthetic functioning, while photosynthesis is affected by the plant's internal and external environment. In wetlands, many environmental factors influence plant functioning including periodic or permanent flooding, periodic drought, salinity, and extreme temperatures. However, soil flooding, the predominant feature of all wetlands, leads to the production of various substances known as "phytotoxins," which are by-products of soil anoxic conditions (see Reddy and DeLaune 2008 and the references cited therein). Therefore, assessment of plant responses to flooding and the associated by-products is critical to understanding of the range, threshold, and optimal conditions for plant growth and productivity in wetlands.

Wetland plants possess characteristics that enable them to survive soil saturation and the soil chemistry related to anaerobic conditions. The literature reveals a range of photosynthetic sensitivities to soil anoxia among wetland species. Initial reductions in net photosynthesis immediately after soil flooding are common among species representing various wetland ecosystems including marshes, forested wetlands, and riparian wetlands. At the whole-plant level, reductions of photosynthetic rate in flooded conditions are attributed to many factors including diffusional limitations due to stomatal closure and to metabolic (non-stomatal) inhibition of photosynthesis (Pezeshki 2001). Soil anoxic condition may lead to photosynthetic reduction due to decreased leaf water potential resulting from root dysfunction, reduced activity of major photosynthetic enzymes, disruption in photosynthate transport, alteration in source-sink relationship, and reduced sink demand (Pezeshki 1994, 2001). Furthermore, while root oxygen deficiency may partially account for the reduction in net photosynthesis, soil phytotoxins produced as by-products of soil flooding may play a major role in photosynthetic sensitivities. Clearly, the high oxygen demand in soil resulting from intense reduction exerts a profound influence on oxygen transport and release to the rhizosphere.

Overall, many wetland plants may suffer short-term to long-term stresses leading to physiological dysfunctions. The so-called "flood-tolerant" plants (hydrophytes) possess features that enable them to tolerate or avoid stresses including anatomical/morphological and physiological adaptations (Fig. 1). Anatomical/morphological adaptations include adventitious roots, stem hypertrophy, aerenchyma tissue formation in root and shoot, lenticels, knees, and pneumatophores (Mitsch and Gosselink 2007). Some examples of these structures include bald cypress' knees and mangrove's pneumatophores that protrude from the soil. Physiological adaptation features include anaerobic respiration, reopening of stomata, and rapid recovery of photosynthetic activity.

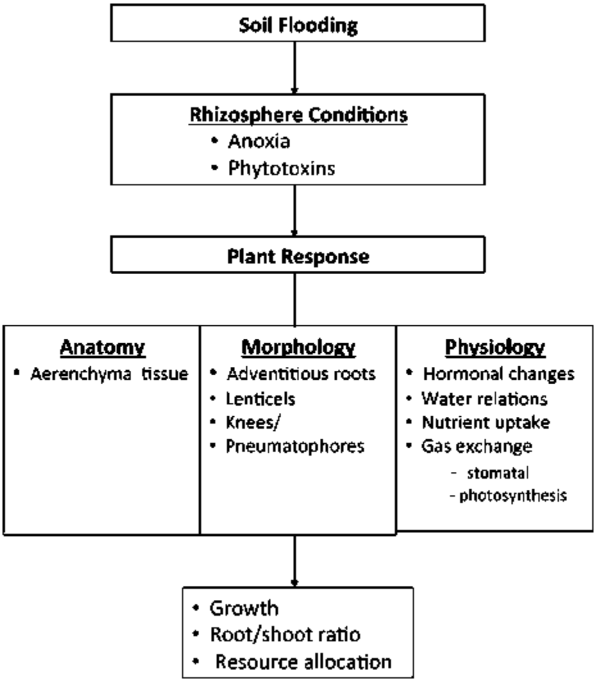

Fig. 1 The relationship between flood-induced changes in soil and rhizosphere conditions, wetland plant functioning, and the potential consequences for photosynthetic carbon fixation and growth

In the following sections, the effects of flooding on soils, the subsequent effects on plant photosynthetic functioning, plant response mechanisms, and the consequences for plant nutrition, photosynthesis and growth are reviewed.

Photosynthesis and Wetland Environment

Life on Earth is dependent on the photosynthetic process, a process by which light energy is converted to chemical energy. Carbon fixed in the photosynthetic process is a significant component of standing plant biomass. CO_2 uptake via the leaf occurs through openings in the leaves known as stomata (also see chapter "▶ Anatomy of Wetland Plants") allowing diffusion in the intercellular spaces of the leaf to the sites of fixation. CO_2 is then fixed via two main pathways known as C_3 or C_4 pathways although C_3 pathway is more common in wetland plants. The designation refers to the first stable compound that is formed in the process, a three-carbon compound in C_3 plants known as phosphoglycerate. In C_4 plants, the first compounds are four-carbon compounds oxaloacetate and malate. Many wetland plants utilize C_3 pathways; however, some wetland plants, many of which found in brackish and salt marshes, are C_4 plants including *Spartina alterniflora*, *S. foliosa*, and *Phragmites australis* (see Mitsch and Gosselink 2007 for details).

Optimal conditions for photosynthesis require, in addition to light and optimal temperatures, adequate supply of nutrients and water. However, in most wetlands, the conditions are less than optimal due to the harsh environment that imposes many unfavorable conditions. Such conditions include flooded soils and the associated anoxic conditions found in many wetlands. Wetland plant roots are the first organ that is exposed to the stress; thus, in the following section, the root environment (rhizosphere) following flooding will be discussed.

Effect of Flooding on Soils

Soil flooding initiates a chain of reactions leading to reduced soil conditions. The reactions encompass various physical, chemical, and biological processes that have significant implications for wetland plants. After flooding is initiated, the limited supply of oxygen is depleted by roots, microorganisms, and soil reductants. Oxygen depletion results in a series of soil chemical changes that include accumulation of CO_2, N_2, H_2, and methane (Mitsch and Gosselink 2007; Reddy and DeLaune 2008). The processes that follow include denitrification; reduction of iron, manganese, and sulfate; and changing soil pH and redox potential (Eh). In a typical series of reductions, NO_3^- is reduced to NO_2^-, Mn^{+4} to Mn^{+2}, Fe^{+3} to Fe^{+2}, and SO_4^{2-} to H_2S, S^{2-} or HS^- (depending upon the soil pH) and accumulations of acetic and butyric acids produced by microbial metabolism (also see ► Chap. 31, "Microbially Mediated Chemical Transformations in Wetlands"). As a result of these transformations, soil redox potential (Eh) becomes progressively more negative. For example, drained soils typically have Eh > +400 millivolts (mV), while waterlogged soils may exhibit Eh levels as low as −300 mV (for details see Mitsch and Gosselink 2007; Reddy and DeLaune 2008).

Soil Flooding and Wetland Plant Functioning

Typically, plants respond to soil physicochemical changes in flooded soil. These responses may lead to a wide range of stress symptoms including root dysfunctions, stomatal closure, and reduced photosynthetic rates (for reviews see Pezeshki 1994, 2001). Flooded soils lead to high competitive oxygen demand, which may affect internal plant tissue oxygen concentration. Other consequences of soil flooding include changes in availability and/or concentrations of nutrients essential for plant functioning and the production of a host of by-product compounds, many are known to be phytotoxic. Examples of such compounds include reduced forms of Fe and Mn, ethanol, lactic acid, acetaldehyde, and aliphatic acids such as formic, acetic, butyric acids, and cyanogenic compounds (for a comprehensive review see Reddy and DeLaune 2008). For instance, excess soil soluble sulfide species are toxic to the roots and are known to inhibit growth of various marsh macrophytes (Pezeshki 2001), while the organic acids have a variety of adverse effects on plants (Reddy and DeLaune 2008).

Anatomical and Morphological Responses of Plants

In many wetland species, an extensive air-conducting tissue (aerenchyma tissue) develop in roots, stems, and leaves in response to flooding. This system allows a plant to transport oxygen to the roots for maintaining aerobic respiration and to oxidize reducing compounds in the rhizosphere. In addition, the internal system of large gas spaces also reduces internal volume of respiring tissues and oxygen consumption, thus enhancing the potential for oxygen reaching the distant underground portions of the plant (Armstrong et al. 1996) (also see chapter "▶ Anatomy of Wetland Plants"). Due to such advantages, the oxygen transport system is an important mechanism to deal with soil anoxia (see Pezeshki 2001 for details and additional references). When flooded, root and rhizomes of wetland species obtain oxygen via gas-phase transport from the shoot system from internal photosynthetic oxygen or atmospheric oxygen. Diffusion, while the major pathway of root aeration in wetland plants, is not the only means of oxygen transport; rhizomes of some species can ventilate via pressurized through flow of gasses (Mitsch and Gosselink 2007).

Despite the reported increase in aerenchyma tissue (and hence porosity) in wetland species in response to flooding, the increase may not be sufficient to satisfy the root respiratory needs for oxygen due to the greater radial oxygen loss rates in reduced soils. For example, continued oxygen stress in the roots of several wetland species was indicated by a rise in alcohol dehydrogenase activity despite the development of aerenchyma tissue (see Pezeshki and DeLaune 2012 and the references cited therein).

Morphological responses include adventitious roots formation on the flooded portions of the stem reported for many wetland plants (also see ▶ Chap. 44, "Wetland Plant Morphology"). These roots play a critical role in supplying oxygen and nutrients to flooded plants as the original roots die in response to sudden flooding (Mitsch and Gosselink 2007). These responses have been reported for many woody wetland species (e.g., *Salix* spp.) as well as herbaceous species (such as *Ludwigia* spp.). Removal of adventitious roots leads to reductions in growth indicating the functional importance of these roots. Such roots replace the losses that occur due to the damaged functioning of original roots in response to flooding. Other morphological responses to flooding include lenticels, small pores (openings) that usually form above the water level on the stem and help with internal plant aeration. Lenticels apparently serve as a conduit for air diffusing into aerenchyma tissues and have been reported for numerous wetland woody species.

Stem hypertrophy, knees, and pneumatophores are among the other morphological responses to flooding. Hypertrophy or stem-base swelling caused by collapse or enlargement of cells in the cortex has been reported in many species (Pezeshki 1994). Knees of bald cypress (*Taxodium distichum*) and pneumatophores are formed on some mangroves (*Avicennia* spp.) are examples of morphological responses to flooding. These structures are thought to be important in aeration of the flooded roots, thus help a wetland plant maintain important root functions. For example, bald cypress knee development may be related to the nature of flooding (Pezeshki 1994; Mitsch and Gosselink 2007).

Plant Nutrition in Flooded Soils

Proper nutrition is critical for optimal photosynthesis; however, nutrient availability is adversely influenced by soil flooding and the associated anoxic soil conditions. Despite wetland plant adaptations, various nutritional deficiencies and toxicities may occur. Flooded soil conditions may lead to inhibition of nutrient uptake and transport due to root dysfunction and/or death, while blockages in the vascular and aerenchyma systems may result from tissue damage due to phytotoxin damage (Armstrong et al. 1996; Pezeshki 2001; Pezeshki and DeLaune 2012).

In some wetland species, ion uptake may continue partly because of the internal O_2 supply system, but partial anoxia in roots can reduce solute intake. Nutrient concentrations at toxic levels may be accumulated in tissues due to higher availability of certain nutrients and root dysfunction. For example, during prolonged flooding, soil pH decreases and zinc availability increases leading to increased tissue zinc concentration. Under such conditions, ferric and manganic forms are reduced to soluble ferrous and manganous forms. Thus, tissue Mn and Fe concentrations in flooded plants are greater than those in aerated conditions. Leaf discoloration (bronzing) due to high soluble ferrous iron has been reported in some species (for reviews see Pezeshki 2001; Pezeshki and DeLaune 2012).

Sulfide toxicity may also occur due to soil chemical changes that include reduction of sulfate to sulfide by anaerobic microorganism. Sulfide is considered to be phytotoxic, although, in most cases, wetland plants can oxidize sulfide in the rhizosphere, thus avoiding or minimizing injury to tissues. Nevertheless, there are numerous reports confirming that excess soil sulfide inhibits growth of various marsh species. The soluble sulfide species including H_2S are toxic to the roots (see Armstrong et al. 1996; Pezeshki 2001). The inhibitory effect of H_2S on cytochrome oxidase is disruptive to aerobic respiration, and excess cytosolic Fe and Mn is harmful to enzymatic structures (Drew 1990). The inhibitory effects of elevated sulfide concentrations on leaf photosynthetic capacity have been demonstrated in several wetland species (see Pezeshki 2001 for additional references). The decrease in photosynthetic capacity has been attributed to disruption of light reactions and/or photophosphorylation and alterations in activity of photosynthetic enzymes. Sulfide has been implicated as a factor responsible for decreased plant growth and productivity in several wetland species (Pezeshki and DeLaune 2012).

Plant Water Relations and Photosynthesis

Whole-plant water relation is influenced by soil flooding as root water uptake in flooded soils is slower than under aerated conditions. Under flooded conditions, internal water stress and leaf dehydration may develop in some species due to a decrease in root permeability leading to stomatal closure and decreased transpiration (also see ► Chap. 45, "Physiological Adaptations to Wetland Habitats"). Many wetland species initially close stomata in response to flooding; however, rapid stomatal reopening may occur. The degree of resumption of stomatal functioning

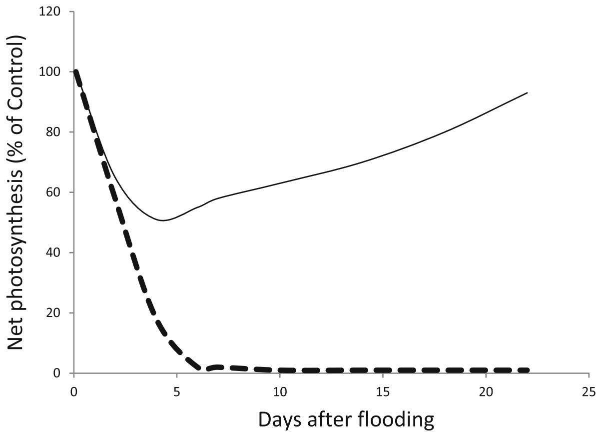

Fig. 2 Effect of initiation and continuation of flooding on photosynthetic activity in two groups of species with different levels of flood sensitivities. Group I represents flood-insensitive species (*continuous line*), while Group II representing flood-sensitive species (*dashed line*). Note the initial reduction in photosynthetic activity for both groups upon initiation of flooding followed by speedy recovery of photosynthetic activity in Group I (despite the continuation of flooding), while little or no recovery is noted in Group II (Data from Pezeshki 1994, 2001)

appears to be dependent on species, duration of flooding, and the intensity of soil reduction (see Pezeshki 2001 and the references cited therein).

Decreases in transpiration and photosynthetic activity have been reported for a number of wetland species in response to flooding. However, substantial differences are found in subsequent photosynthetic responses under continuous flooding among wetland species (Fig. 2). The initial photosynthetic decline has been attributed to diffusional limitations on gas exchange due to stomatal closure and metabolic (non-stomatal) inhibition. However, the contribution of each component to such a response varies across species. In response to flooding, a shift in photosynthetic light-response curves was noted in some species suggesting direct adverse effects on the photosynthetic capacity of the leaves. Photosynthetic recovery is initiated in some wetland species even during prolonged flooding (Fig. 2). Nevertheless, the impact of the apparent delayed and/or slow recovery on plant growth may be substantial due to the initial disruption of carbon fixation and decrease in photosynthate production (Pezeshki 2001).

The adverse initial effects of flooding on stomatal functioning and photosynthetic capacity of many wetland species are well documented (Fig. 3); however, numerous mechanisms may be involved. For example, ethylene has been implicated in the decline of leaf photosynthetic capacity. The effects may be due to loss of photosynthetic capacity of mesophyll. Furthermore, root zone anoxic conditions may lead to reductions of photosynthesis due to decreased leaf water potential, reduced rubisco activity (Pezeshki 1994), disruption in photosynthate transport, alteration in source-sink relationship, or reduced sink demand (Drew 1990; Pezeshki 2001). Other factors may contribute to the reduction in photosynthetic capacity including low

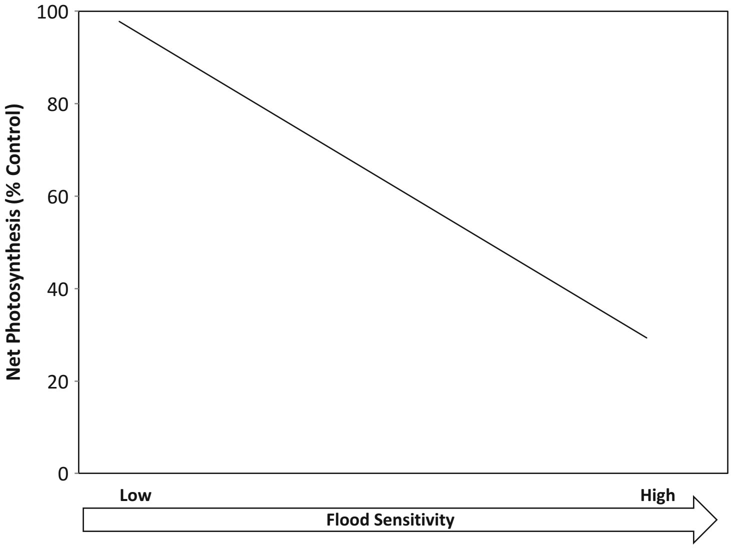

Fig. 3 A generalized relationship between photosynthetic activity and flood sensitivity for wetland plants (Redrawn from Pezeshki 1994)

leaf chlorophyll content and/or leaf chlorophyll degeneration. Leaf chlorophyll content decreased only in some wetland species subjected to flooding (for review see Pezeshki 2001).

As mentioned earlier, reduction in activity of photosynthetic enzymes has been reported in response to flooding including changes in activity of rubisco (see Pezeshki 1994, 2001 for detailed reviews). Stress factors can reduce rubisco activity and/or enhance rubisco degradation in some species. Because activity of this enzyme is critical for photosynthesis, flood-induced reductions of net photosynthesis may be due, at least partially, to decreased rubisco activity. In addition, the recovery of rubisco activity may contribute to the resumption of photosynthesis in some wetland species (Pezeshki 1994, 2001).

Flooding also influences translocation of various photosynthetic products. For example, reduced rates of assimilate translocation to roots has been reported for some species. The effects include low ATP production resulting from disruption of the oxidative phosphorylation (Kennedy et al. 1991), carbohydrate synthesis, transport, allocation, and utilization. Carbohydrate allocation patterns and translocation rates may be a critical aspect of flood tolerance, but this issue requires further research in wetland species.

Growth and Biomass Production

Decreased biomass accumulation often occurs in wetland species in response to flooding. Also, root/shoot ratios often decrease with flooding, because the effect of

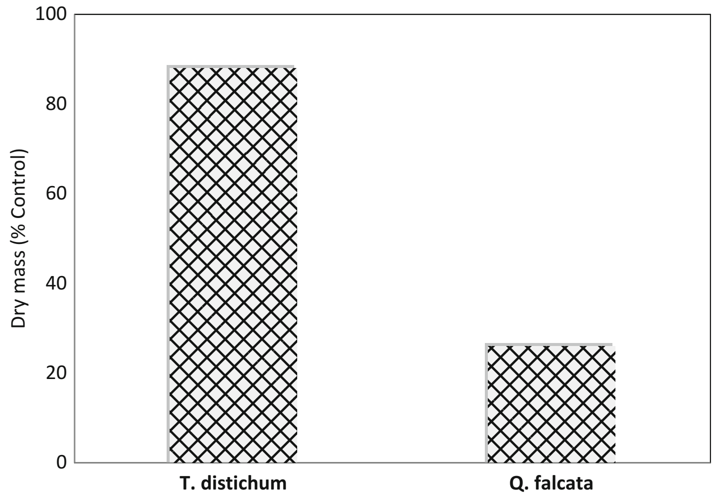

Fig. 4 Effect of flooding on growth (dry mass accumulation) of seedlings of two woody species with different levels of flood sensitivities. *Taxodium distichum*, a flood-tolerant species, and *Quercus falcata* var. *pagodifolia*, a flood-sensitive species. Seedlings were grown in a greenhouse and subjected to non-flooded drained (control) or continuously flooded treatments (Redrawn from Fig. 5, Pezeshki and Anderson 1997)

soil reduction on root growth is often very negative. While a range of responses to soil flooding may occur in a given species, these changes, nevertheless, occur within the context of an overall reduction in biomass accumulation (Fig. 4) as reported for flooded individuals of many species (see Pezeshki 2001 and the references cited therein). For example, root dry weight decreased by 40%, while shoot dry weight reduced by 25% in *Spartina patens* as soil reduction intensified following flood initiation. In general, soil reduction has pronounced effects on root elongation. Similar conclusions were drawn from a study on a flood-tolerant woody species *Taxodium distichum*. Additional data showed cessation of root growth in *Spartina patens* and noted smaller root system under anoxic soil conditions (see Pezeshki and DeLaune 2012 for details). Since roots are major sink for photosynthetic products, such reduction in sink size may in part be responsible for a negative feedback inhibition of photosynthesis, thus reduction in productivity of this species.

The increase in root oxygen loss rates reported under flooded soil conditions may explain the reductions in root growth of several wetland species including *Cladium jamaicense* and *Typha domingensis*. These wetland species produced significantly less biomass under sustained flooding as compared to plants grown in oxidized sediments (see Reddy and DeLaune 2008 and the references cited therein). Root growth is an energy-dependent process requiring oxygen; thus, under flooded conditions, root functioning is affected rapidly because molecular oxygen is required as an electron acceptor for oxidative phosphorylation (Drew 1990). Root elongation was inhibited in some species when soil became anoxic. Root penetration depth was also adversely affected under anoxic soils leading to development of shallow root system different in architecture than those of plants growing in aerated sediments (see Pezeshki 2001 for review).

Future Challenges

Assessment of wetland plant carbon fixation in response to environmental factors is critical to the understanding of wetland functioning. Plant growth depends on photosynthetic process, while photosynthesis in turn is affected by plant's internal mechanisms and external factors. In wetlands, many environmental factors influence plant functioning. These factors alone or in combination include flooding, periodic drought in certain wetlands, salinity in coastal wetlands, and extreme temperatures in some wetlands. However, soil flooding, the predominant feature of all wetlands, leads to the production of various substances known as "phytotoxins" that are by-products of soil anoxic conditions. The contribution of "phytotoxins" to the overall observed photosynthetic reductions in plants in flooded soils, as well as plant response mechanisms, remains as major areas of challenge for the future. In addition, wetland plants are likely to be subjected to additional complex sets of environmental stressors if the predicted future climate changes are realized (also see ► Chap. 2, "Succession in Wetlands"). Such changes include higher temperatures, increased atmospheric CO_2, excess salinity due to sea level rise in coastal wetlands, and prolonged drought in some interior wetlands. These factors alone and in combination pose new challenges for research that should encompass evaluation of plant responses to these predicted scenarios.

Photosynthetic Measurements in Wetlands 35

S. Reza Pezeshki

Contents

Abstract

Assessment of wetland plant photosynthetic carbon fixation in response to environmental factors is critical to the understanding of wetland functioning. Various approaches including utilization of the methods described in the present paper is essential to the evaluation process. Advances in development of equipment, particularly field portable systems, in recent decades have led to excellent opportunities to conduct research in the field. The present paper focuses on several methods currently available for direct and indirect photosynthetic measurements. The advantages and disadvantages of each technique along with examples of currently available equipment are briefly mentioned while additional key references are provided for the readers to follow the details elsewhere.

Introduction

Plant photosynthesis and productivity in wetlands may be quantified by various techniques. For example, periodic harvests of biomass is one way to assess measurements of changes in productivity, which is an important indicator of photosynthetic carbon fixation. Destructive sampling is used for productivity assessment over a few weeks to an entire growing season. This method is a popular approach for assessment of plant productivity and for comparing across a range of environmental conditions in wetlands. In forested systems, nondestructive litterfall traps and wood production are used more often than harvesting to assess photosynthesis. Numerous studies have reported productivity estimates for marshes based on the standing crops obtained by various harvest methods (see Cronk and Fennessy 2001 for a detailed review).

There are, however, shortcomings associated with harvest methods. For example, the technique usually incorporates changes in live and dead materials during different intervals; however, harvest methods do not account for the physical removal of organic matter between harvests or loss through decomposition leading to an underestimate of productivity. Other harvest approaches to measurement of net primary productivity of emergent herbaceous wetland plants may overestimate or underestimate productivity. Furthermore, the technique is not appropriate when evaluation of short-term plant responses, i.e., hours or a few days, to changes in the environment is required. In such cases, the measurement of photosynthetic carbon fixation allows nondestructive, direct assessment of plant functioning and extrapolation of the data to show the potential for dry weight accumulation.

Quantifying photosynthetic carbon fixation is a useful approach for assessment of plant productivity. In the past, this technique was not a preferred method in the field because of technical difficulty in operating complex equipment, which required a power source and stable temperature for operation of the equipment. Using this equipment in wetlands necessitated the use of portable laboratories as was the case for other ecosystems, such as terrestrial ecosystems (Field et al. 1992). Additional advances made in building battery-operated, light-weight portable photosynthetic systems facilitated the use of photosynthetic measurements in productivity assessment in wetlands.

There are a number of methods available for quantifying plant photosynthetic responses at leaf, branch, whole-plant, and canopy levels. These techniques include measurement of oxygen (O_2) exchange, stable- isotope method, micrometeorological technique (eddy correlation), chlorophyll fluorescence, and the efficiency of Photosystem II (PSII) method, simple chamber with remote carbon dioxide (CO_2) analyzer, and portable chambers using onboard infrared gas analyzers (IRGA). This section focuses on these techniques and their utilization for measuring photosynthesis in wetlands. The advantages and disadvantages of each technique along with examples of currently available equipment are briefly discussed (see Pezeshki 2013 for additional details).

Measurement Techniques

Oxygen Exchange Measurements

Photosynthesis involves conversion of light energy to chemical energy by chlorophyll. During a series of reactions, CO_2 is taken up while O_2 is evolved from the plant. Thus, photosynthesis can be measured as either CO_2 uptake or O_2 evolved. The O_2-exchange measurement technique is based on the principle that a leaf enclosed in a chamber and supplied with carbon dioxide produces O_2 upon illumination. The accumulated O_2 in the chamber is measured using a Clark-type O_2-electrode. The measurements are then converted to CO_2 uptake per unit leaf area per unit time (such as μmol CO_2 m^{-2} leaf s^{-1}) through a series of calculations. The measurement is relatively simple using commercially available instruments.

The advantages of using this technique include the availability of relatively inexpensive portable units that can be used in the laboratory as well as in the field. The major limitations include the need for destructive sampling as well as many of the limitations due to the use of small leaf cuvettes including extrapolation of data to whole-plant and canopy level carbon fixation assessment.

Carbon Isotope Technique

Use of CO_2-labeled with a carbon isotope (^{14}C) for photosynthetic research is well established in the literature. A leaf that is exposed to air containing $^{14}CO_2$ incorporates ^{14}C into photosynthetic products. Thus, the technique allows assessment of photosynthetic carbon fixation. In a typical system, a cylinder that contains a known $^{14}CO_2/^{12}CO_2$ gas mixture is connected to a chamber. A leaf or plant part is exposed to the gas in the chamber for a brief period of time and measured precisely. The tissue is then removed, frozen in liquid N_2, and processed for determination of $^{14}CO_2$ content using a liquid scintillation counter. There are different systems that are specifically designed for laboratory or field application (see Field et al. 1992).

This technique is a useful approach; however, its limitations include the need for destructive sampling that is followed by significant laboratory tissue analyses adding to the complexity of the methodology as well as limitations associated with extrapolation of data from small leaf samples to whole-plant and canopy levels.

Micrometeorological Techniques

Carbon dioxide fixation by a stand of plants can be measured over a large area using micrometeorological techniques that do not require destructive sampling or any enclosure. Accordingly, the CO_2 exchange rate is quantified using air movements and CO_2 concentrations above a stand of plants. The technique known as eddy correlation (also referred to as eddy covariance) is an indirect measure of ecosystem productivity. Eddies are defined as layers of air that move as units carrying various gases such as CO_2 into and out of an ecosystem; thus within these units, gas concentrations are uniform. Once an eddy passes over a canopy surface, CO_2 diffuses from the eddy into the photosynthesizing canopy. Because photosynthesis removes CO_2 from the air immediately surrounding the plant tissue, the adjacent air layer is replaced with ambient CO_2 level. Therefore, the technique allows measurement of net CO_2 transfer into or out of an ecosystem.

The technique requires extensive equipment such as infrared gas analyzers (IRGA), computers, and data loggers to allow continuous data collection on the CO_2 gradient and airflow for determination of the photosynthetic rates. Thus, the rate of CO_2 uptake by plants is assumed to be equal to the rate of CO_2 supplied from the ground below the canopy and from the atmospheric air above the canopy (Field et al. 1992). Clearly, utilizing eddy correlation technique to assess wetland productivity can provide useful information, and it has already produced such information in other ecosystems (see Goulden et al. 2004).

The disadvantages of using the micrometeorological technique include lack of control over environmental factors and the expense of an elaborate field set up to allow continuous and concurrent measurements of air flow, CO_2, and other parameters. Also, the productivity measurement obtained is not a direct estimate of net primary productivity because it includes contributions from all CO_2 sources and sinks within an ecosystem. Nevertheless, the technique is very useful in the assessment of community level carbon fixation.

Chlorophyll Fluorescence Method

The usage of chlorophyll fluorescence to measure Photosystem II (PSII) efficiency is based on the principle that light energy absorbed by chlorophyll molecules are used to: (1) drive photosynthesis (referred to as photochemistry), (2) form excess energy that is dissipated as heat, or (3) reflected as light (chlorophyll fluorescence). The three processes are competing processes, i.e., an increase in the efficiency of one would lead to decrease in other processes. Thus, by measuring the yield of chlorophyll fluorescence, information about changes in photochemistry and heat dissipation is obtained (see Maxwell and Johnson 2000; Lichtenthaler et al. 2005, and Henriques 2009 for detailed reviews and additional references).

In recent years, advances have led to the design of “modulated fluorometers.” These systems allow assessment of PSII in the presence of other light sources including sunlight. Modern modulated fluorometer units from various manufacturers are portable and can be used in the field, with subsequent chlorophyll fluorescence data downloaded and analyzed.

The chlorophyll fluorescence measurements yield useful information on photosynthetic performance providing insights into plant stress and tolerance mechanisms. The technique is most useful for early detection of stress before visible effects become apparent. Although measurements of chlorophyll fluorescence can provide critical information on light energy absorption and conversion that occur in photosynthesis, direct extrapolation from these data to the carbon fixation of an individual plant requires caution. For example, the technique does not allow valid comparison between control and stressed plants when visible leaf color changes occur in response to a given stress (see Henriques 2009 for details and additional references).

Photosynthetic Measurements Utilizing Chambers

Plant carbon fixation studies utilizing chambers encompass a range of enclosures such as miniature cuvettes for leaf-level measurements to large tree enclosures. The rate of CO_2 fixation by the leaves in a chamber is calculated from the CO_2 concentration difference between the incoming air prior to exposure to plant material and the outgoing air after exposure to the plant.

Simple Chamber Technique

Use of a simple chamber for measurements of photosynthetic activity using a remote gas chromatograph (GC) or infrared gas analyzer (IRGA) includes a system for photosynthetic measurement in a wetland (see Reddy and DeLaune 2008 for details). This approach is based on the principle that the rate of CO_2 fixation by the leaves in a chamber is calculated from the CO_2 concentration changes in the chamber over time. In the dark chamber, only respiration is occurring resulting in an increase in CO_2, whereas in the light chamber both photosynthesis and respiration occur at the same time. Thus, utilizing both chambers provides an estimate of photosynthetic rate after adjusting for respiration. This approach is a useful method to study plant photosynthesis in wetlands. The system is relatively simple, easy to build, and economical. Thus, if replicated over a reasonable area of marsh and utilized carefully, it can produce useful comparative estimates of wetland productivity.

Portable Gas Exchange Systems Using Infrared Gas Analyzers

This approach is based on the principle that the rate of CO_2 fixation by the leaves in a chamber can be calculated from the CO_2 concentration changes in the chamber over time. This photosynthetic system includes one or more Infrared gas analyzers (IRGA). Because CO_2 is a strong absorbent of infrared radiation within a certain range, IRGA can measure CO_2 concentration of the air passing through the system. The leaf chambers are designed to control the internal chamber's environment including airflow, temperature, relative humidity, CO_2 concentration, and light level.

Modern photosynthetic systems have built-in automated data acquisition and recording. These devices allow the researcher immediate access to the raw and processed data of measured and/or calculated parameters, which can be downloaded to a computer. In addition, the system also measures plant transpiration to calculate stomatal conductance (g_{wv}) for determining the internal leaf CO_2 concentration (C_i). Calculation of C_i is important because it represents the availability of CO_2, the primary substrate for photosynthesis. Thus, C_i data is critical for determining the limitations to photosynthetic activity due to reductions in diffusion caused by stomatal closure (stomatal limitation) versus the biochemical limitations (nonstomatal limitation) that result from changes in photosynthetic efficiency (see Woodrow et al. 1987 for details).

In wetlands, portable gas exchange systems may be utilized to study plant responses to changes in environmental conditions (Pezeshki 2001). In addition, this method can also be used to assess wetland plant health and functioning and to estimate wetland productivity. Nonetheless, these systems provide leaf-level data. As such, one must make many assumptions to extrapolate the data to the whole-plant, population, and community levels. However, leaf-level measurements are useful fir understanding of the whole-plant level, particularly if coupled with measurements that represent carbon fixation above the whole-plant level. Photosynthetic measurement at higher levels such as the whole-plant or canopy is possible using whole-plant chambers or other techniques mentioned previously. Canopy chambers and micrometeorological techniques can provide information related to the effect of species composition on productivity although each of these techniques has limitations as mentioned in previous sections.

Future Challenges

Assessment of wetland plant carbon fixation in response to environmental factors is critical to the understanding of wetland productivity and functioning. Such assessment requires the utilization of various approaches including the use of one or more of the methods described above. Continuous advances have been made in developing instruments that are portable and useful in the field. However, many challenges remain since the majority of the techniques provide leaf-level data, which are difficult to extrapolate to the whole-plant, population, and community levels. Canopy chambers and micrometeorological techniques can provide information related to the effect of species composition on productivity although each of these techniques has limitations as well. Additional advances in techniques are needed to improve the accuracy and the overall assessment at the community and ecosystem levels.

36 Primary Production and Respiration: Ecological Processes in Wetlands

M. Siobhan Fennessy and Julie K. Cronk

Contents

Abstract

Wetland primary production is a measure of ecosystem metabolism. It quantifies the amount of carbon fixed in the process of photosynthesis and released in the process of respiration by the plants and algae (photosynthetic organisms) in the ecosystem. At the ecosystem level, the total amount of carbon captured and stored via photosynthesis is known as gross primary production, or GPP. Respiration is the cellular process in which the chemical energy contained in organic compounds is converted to useful energy (in the form of adenosine triphosphate, ATP) to maintain cellular activity. The balance of these two processes represents the net carbon fixed into organic compounds, or net primary production (NPP), which can be used to build biomass.

Introduction

Wetland primary production is a measure of ecosystem metabolism. It quantifies the amount of carbon fixed in the process of photosynthesis and released in the process of respiration by the plants and algae (photosynthetic organisms) in the ecosystem. At the ecosystem level, the total amount of carbon captured and stored via photosynthesis is known as gross primary production, or GPP. Respiration is the cellular process in which the chemical energy contained in organic compounds is converted to useful energy (in the form of adenosine triphosphate, ATP) to maintain cellular activity. The balance of these two processes represents the net carbon fixed into organic compounds, or net primary production (NPP), which can be used to build biomass. NPP can be calculated as:

$$\mathrm{NPP} = \mathrm{GPP} - \mathrm{R}$$

Information on primary production is essential to understanding the functions and ecosystem services that wetlands provide (Cronk and Fennessy 2001), and data on primary production are often the basis for quantitative studies of other ecosystem processes. For example, knowledge of primary production can provide insight into the trophic dynamics of an ecosystem as well as the cycling and retention of plant nutrients. Primary production leads to the provision of many ecosystem goods, such as fish and shellfish, timber, biomass fuels, fiber, and pharmaceuticals (Daily 1997). In addition, primary production affects soil oxygen levels and can be an important factor in determining oxidation-reduction conditions in wetland sediments.

The organisms that carry out photosynthesis are known collectively as primary producers, or autotrophs. Photosynthetic organisms of all types play a number of vital roles in wetland ecosystems. The following is a summary of their contributions in terms of primary production (Cronk and Fennessy 2001):

- Autotrophs form the base of the food chain and, as such, are the major conduit for energy flow into the wetland biota. Primary production of wetland plant communities varies, but some herbaceous wetlands have extremely high levels of production, rivaling those of tropical rain forests.
- Submerged photosynthetic organisms release dissolved oxygen into the water column, making it available for uptake by other aquatic organisms. They also release carbon compounds, and thereby influence the wetland plant, algal, microbial, and animal communities.
- The photosynthetic organisms of wetlands strongly influence water chemistry, acting as both nutrient sinks through uptake, and as nutrient pumps, moving

compounds from the sediments into the biomass. They improve water quality by taking up nutrients, metals, and other contaminants, and by providing organic substrates for microbial processes such as nitrification and denitrification.

In addition to their trophic and chemical roles, the vascular plants of wetlands provide critical habitat for other taxonomic groups, such as bacteria, epiphyton (algae that grows on the surface of plants), macroinvertebrates, fish, and birds. The composition and diversity of the plant and algal communities have a strong influence on the overall diversity of the wetland faunal community. In addition, plants influence wetland hydrology and sediments by stabilizing shorelines, and modifying currents. They also influence peat accumulation, shade the water column thus stabilizing water temperatures, and affect water cycling via evapotranspiration.

Cellular Metabolism: Photosynthesis and Respiration

The conversion of solar energy into stored, chemical energy in plant cells is known as photosynthesis. While the pathway that converts carbon dioxide and water into sugars and oxygen is a complex process, the overall reaction can be expressed in this chemical equation:

$$6CO_2 + 12H_2O \xrightarrow[\text{chlorophyll}]{\text{light energy}} C_6H_{12}O_6 + 6O_2 + 6H_2O$$

The sugars produced in this process provide both energy and the building blocks for larger biological molecules that form plants' structures. The oxygen is released into the air or water and can be taken up by other organisms in aerobic cellular respiration. Photosynthesis can be measured by carbon dioxide assimilation or oxygen production. Algal and submerged plant production can be estimated by measuring the dissolved oxygen levels in the water column. Production changes throughout the day as well as seasonally due to light, carbon dioxide, and nutrient availability.

Respiration is the cellular process in which chemical energy contained in biomolecules (sugars, lipids, and proteins) is oxidized. Cells convert the released energy into a chemical form (ATP) that is directly usable by cells. The chemical equation for the aerobic respiration of glucose is essentially the reverse of the equation for photosynthesis. While photosynthesis is limited to periods of light, respiration takes place at all times.

Aerobic cellular respiration can be measured by carbon dioxide evolution or oxygen consumption by a plant or portion of a community. For example, researchers can enclose the sample in a chamber and measure the changes in gas concentrations in the air or water that surrounds it. Respiration rates can be quite high and can "undo" a large portion of the carbon fixed in photosynthesis. In a review of primary production in wetlands, the average rate of respiration in emergent wetlands was estimated to amount to 72% of GPP (Brinson et al. 1981). As with photosynthesis, respiration rates are highly variable and change with temperature and the availability of water, oxygen, and energy compounds.

Measuring Primary Production

Primary production is typically measured as the amount of biomass produced per unit area, where biomass is the mass of plant material. The term, *primary productivity*, refers to primary production over time, or the rate of primary production. If gaseous exchange methods are used to measure primary productivity, the time period is a day or an hour and the units are grams of oxygen evolved or carbon assimilated. In wetland plant studies, results are usually given in units of dry plant matter produced per unit area per year (g dry weight m^{-2} $year^{-1}$). In the temperate zone, growth per year is actually growth during the growing season.

Net primary productivity is a measure of the observed changes in plant biomass over a time period. *Gross primary productivity* includes both net primary productivity and all of the predatory and non-predatory losses (respiration) from the plant divided by the time interval. Net primary productivity is the value most often reported in wetland plant production studies and it is usually reported in units of grams dry weight per square meter per year (g m^{-2} $year^{-1}$); this allows for easy comparison between systems.

Often, measurements of whole wetland primary production reflect a combination of measures because several plant forms coexist within a single wetland. These forms include algae, submerged and emergent plants as well as trees and shrubs. Each component of the community requires different methodology. For example, harvested, cleaned, and dried herbaceous plants can be weighed to gain a measure of biomass. Algal productivity is often measured by oxygen production while tree growth is often measured as a change in trunk diameter. All of these measures need to be converted to the same units and combined in order to reflect whole system productivity.

Measurements of productivity may be single point measures, giving a synoptic view of the ecosystem, or for a more meaningful analysis of productivity, repeated or sequential measures are required. Sequential measures of biomass enable more accurate estimates of net primary production. If sequential measurements are taken, the change in biomass (ΔB) can be calculated as:

$\Delta B = B_2 - B_1$ Change in biomass over the time interval, $t_1 - t_2$

where:

B_1 = Biomass of a wetland at time 1, t_1
B_2 = Biomass at time 2, t_2

If plant losses to mortality or leaf fall (L) and plant losses to grazing (G) can also be measured, then this information can be combined with the change in biomass to estimate net primary production for the given time period:

$$NPP = \Delta B + L + G$$

Table 1 Primary production rates for a range of wetland ecosystem types (From Cronk and Fennessy 2001)

Wetland type	Net primary production g dry weight m^{-2} $year^{-1}$
Salt marsh	130–3700
Tidal freshwater marsh	780–2300
Freshwater marsh	900–5500
Mangrove	1270–5400
Southeastern U.S. bottomland hardwood	830–1600
Cypress swamp	200–1540
Forested northern peatland[a]	260–2000
Non-forested northern peatland[a]	100–2000

[a]Includes above- and belowground production

In all wetland primary productivity studies, detailed descriptions of methods used are needed so that the results can be compared among wetlands.

Wetland Primary Production Studies

The primary production of many wetlands is relatively high, especially when compared to other types of ecosystems or even to highly managed agricultural lands. As Keddy (2000) points out, wetlands do this without the inputs of fossil fuels (in the form of fertilizers and machinery) or irrigation water. They are the workhorses of the landscape, producing biomass and oxygen that support adjacent ecosystems and other species. Many variables influence primary production, such as the type of wetland, species composition, hydrology, climate, and other environmental variables such as soil type and nutrient availability. Table 1 shows a general comparison of mean rates of primary production for different types of wetlands. Note that the range of values within each type is indicative of the wide variation of conditions and climates in which these general categories of wetlands can be found. It is also a reflection of different methodologies, with higher numbers usually indicating not only higher productivity but also combined and sequential measurements.

The length of the growing season and temperatures decrease with increasing latitude, and these factors have a substantial influence on productivity. In boreal wetlands and peat bogs, productivity rates typically range from 100 to 1000 g m^{-2} $year^{-1}$ (Cronk and Fennessy 2001), far less than in tropical or even temperate areas.

Two particularly productive wetland types are freshwater and salt marshes, which are dominated by emergent herbaceous vegetation. A typical high value for the aboveground primary productivity of marshes in temperate zones is 2500 g m^{-2} $year^{-1}$ (although higher rates have been reported). The primary productivity of mangrove forests, which are forested wetlands of the coastal tropics, also is quite high. In fact, the primary productivity of marshes and mangrove forests is at the same level as the primary productivity of highly productive tropical rain forests. Overall, primary production in wetlands globally varies by about a factor of 4, with mean rates ranging from about 500 to 2000 g m^{-2} $year^{-1}$ (Mitsch and Gosselink 2007).

Factors that Control Wetland Primary Production

In addition to climate and latitude, other major influences on wetland primary production are hydrology and nutrient availability. Hydrology is a key forcing function in wetlands and has been called the "master variable" that determines ecosystem structure and function. Wetland hydrology describes the timing, duration, and frequency of inundation, and the resulting hydroperiod (pattern of water levels over time) is an important predictor of both the type of wetland that will develop at a specific location and the productivity of that system (Brinson et al. 1981).

In part, hydrology is important because water carries nutrients and sediments that affect production rates (Keddy 2000). Sites that are open to hydrological fluxes with flowing water and a pulsing (variable) hydroperiod tend to have higher production rates, while stagnant water or nonvariable water levels tend to depress them (other factors being equal; Fig. 1). Studies of the relationship between net primary productivity and flooding regime in wetlands led Odum and others (1995) to propose the "subsidy-stress" model that essentially predicts that too little or too much flooding decreases productivity, while moderate levels (e.g., seasonal flooding) increases it (Fig. 2). In permanently flooded, or stagnant wetlands, anaerobiosis may become extreme and nutrient availability altered. In wetlands with highly abrasive flooding, erosion can carry away sediments, plants, and seeds. Those sites that are "open" to intermediate amounts of hydrological flux tend to be the most productive. Water flows also affect carbon storage by regulating primary productivity, the rate of litter decomposition, and the export organic matter. Tidal wetlands are influenced by twice per day tidal flushing as well as freshwater inputs from adjacent uplands. Primary production in tidal marshes tends to be higher where freshwater inputs are greater (Cronk and Fennessy 2001).

The availability of nutrients can also affect primary production in wetlands. Plant and algal growth tends to be limited by either nitrogen or phosphorus. If the concentrations of these limiting nutrients increase, plant growth, up to some limit, will also increase (Wetzel 2001). Nutrient subsidies occur naturally from water inflows to the site, or as a result of human activities such as farming that lead~~s~~ to nonpoint source runoff of applied fertilizer. Wetlands that receive such inputs tend to have higher primary productivity than those that do not. The least productive wetlands are those that receive nutrients only from rainwater, including some cypress swamps and ombrotrophic bogs.

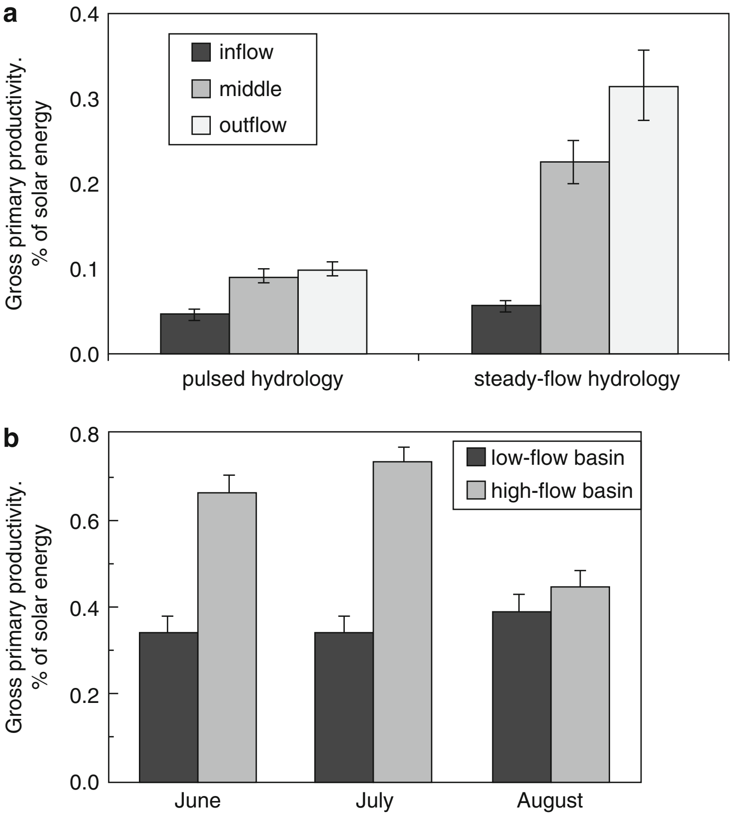

Fig. 1 Differences in algal primary production in the water column as a function of pulsing versus steady state hydrology in experimental wetlands (**a**) the Olentangy River Wetland Research Park in Ohio, and (**b**) the Des Plains River Wetland Demonstration Project (Mitsch and Gosselink 2007). At the Ohio site, pulsed hydrology led to sediment scour and plant damage (abrasive flooding)

Conclusion

Wetland primary productivity varies with climate, hydrology, and nutrient availability and is measured in terms of the amount of biomass produced over a defined time period. Measurements of primary production are vital to understanding the trophic dynamics of wetlands as well as their role in nutrient cycling. They also allow us to compare ecosystem functions among wetlands of all types and between wetlands and other ecosystem types. High rates of primary production support high rates of secondary production and the diversity of higher tropic levels. The provision of ecosystem goods, such as fish and shellfish, timber, biomass fuels, fiber, and pharmaceuticals also depends on the energy harnessed by primary producers

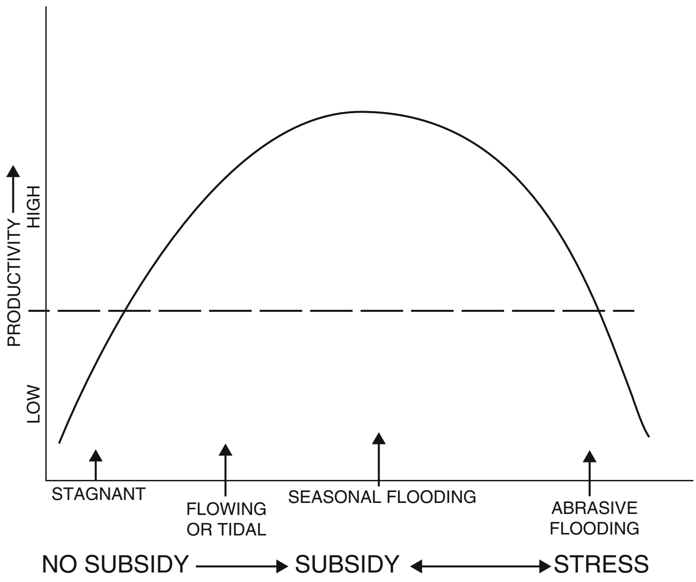

Fig. 2 The subsidy-stress model developed by Odum et al. (1995) showing the pattern of primary production along a hydrological gradient of flooding

(Daily 1997). Understanding primary production enhances our knowledge of the value of wetlands within the landscape.

Contents

Abstract

Wetlands and the ecosystem services they provide are hugely valuable to people worldwide in many ways: for livelihood, for their biodiversity and existence values and for their economic benefits. Yet many of these services, such as the recharge of groundwater, water purification or cultural values are not immediately obvious when one looks at a wetland and most are public services that are not traded in conventional markets. This chapter gives a brief introduction into the concept of wetlands ecosystems services and their values.

Introduction

Wetlands and the ecosystem services they provide are hugely valuable to people worldwide in many ways: for livelihood, for their biodiversity and existence values, and for their economic benefits (MA 2005; TEEB 2010). Yet many of these services, such as the recharge of groundwater, water purification, or cultural values, are not immediately obvious when one looks at a wetland and most are public services that are not traded in conventional markets. Also planners and decision-makers at many levels are frequently not fully aware of the connections between wetland condition and the provision of wetland services and the consequent benefits and economic values. This lack of understanding and recognition leads to ill-informed decisions on management and development, which contributes to the continued rapid loss, conversion, and degradation of wetlands – despite the total economic value of natural wetlands often being greater than that of alternative land uses (e.g., Balmford et al. 2002; de Groot et al. 2010; 2012).

Development of the Concept of ecosystem services

The recognition and study of interactions between the environment and human welfare stretches back centuries and includes writings from Roman times on the increase in population and decline in what we now call ecosystem services (De Groot et al. 2010). In 1977, Westman published a paper in Science examining the link between ecological and economic systems entitled “How much are Nature’s Services Worth?” (Westman 1977). Ehrlich and Ehrlich (1981) later coined the term ”ecosystem services” and in the following decade ecologists further elaborated the notion of ecosystems as life-support systems, providers of ecosystem services and economic benefits. But it was not until the late 1990s that the concept received widespread attention with publications by Costanza et al. (1997) and Daily (1997). At the same time, the interdisciplinary field of ecological economics developed the concept of natural capital (Costanza and Daly 1992), which included non-renewable resources, renewable resources, and ecosystem services to demonstrate the significance of ecosystems as providing the biophysical foundation for societal development and all human economic activity (Common and Perrings 1992).

Based on these and other studies, the Millennium Ecosystem Assessment (MA 2005) recognized four categories of services: provisioning (e.g., food, fresh water, wood and fiber, and fuel); regulating (e.g., climate regulation, flood and disease regulation, and water purification); supporting (e.g., nutrient cycling, soil formation, and primary production); and cultural (aesthetic, spiritual, educational, and recreational). As a follow-up to the Millennium Ecosystem Assessment, a study on The Economics of Ecosystems and Biodiversity was carried out from 2007 to 2011 (TEEB 2010). Since then, many national Ecosystem Services assessments have been and are being carried out, and in 2012 the Intergovernmental Science-Policy Platform on Biodiversity and Ecosystem Services (IPBES) was established.

In spite of all the work done so far, there is still much debate about definitions and classifications and perhaps we should accept that no final classification can capture the myriad of ways in which ecosystems support human life and contribute to human well-being (De Groot et al. 2010).

Description and Examples of Wetland Ecosystem Services

Wetlands provide a broad range of goods and services that are of value to humans. These services are the product of, but should not be confused with, ecosystem processes and functions (Mace et al. 2012). Functions represent the *potential* that ecosystems have to deliver a service which in turn depends on ecological structure and processes (see Fig. 1). For example, primary production (= process) is needed to maintain a viable fish population (= function) which can be used (harvested) to provide food (= service); nutrient cycling (= process) is needed for water purification (= function) to provide clean water (=service). The benefits of these services are manifold, for example, food provides nutrition, but also pleasure and sometimes even social identity (as part of cultural traditions); clean water can be used for drinking, but also for swimming (pleasure) and other activities aimed at satisfying needs and wants. The linkage between ecosystem properties – functions – services – benefits is often presented as a "cascade" (see Fig. 1).

There is not necessarily a one-to-one correspondence between ecosystem functions and services. It might be the case that multiple functions combine to provide a

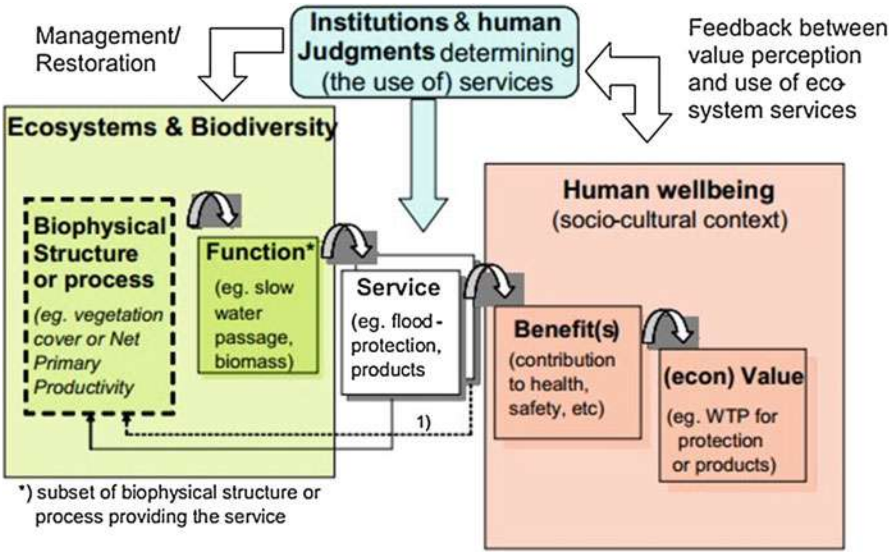

Fig. 1 Linking ecosystem properties to human well-being (source: de Groot et al. 2010; reproduced with permission from United Nations Environment Programme)

single service or that a single function provides multiple services. It is also the case that ecosystem services are combined, to varying extents, with other inputs (e.g., manufactured capital and labour) to produce the services that are consumed by humans. Table 1 lists the main services of inland and coastal wetlands.

Economic Valuation of Wetland Ecosystem Services

The study of wetland ecosystem services is a multidisciplinary undertaking, requiring the understanding of both the ecological provision of services and the socioeconomic benefits that are derived from them. The multidisciplinary study of wetland ecosystem services is, however, challenging due to the differences in paradigms and language across disciplines. In this section, we provide an introduction to the economic understanding of wetland ecosystem services and their values in order to facilitate transdisciplinary understanding.

Economic values associated with wetland ES can be categorized into distinct components of the "total economic value" (see Fig. 2) of wetland natural capital according to the type of use. Direct use values are derived from the uses made of a wetland's resources and services, for example wood for energy or building, water for irrigation, and the natural environment for recreation. Indirect use values are associated with the indirect services provided by a wetland's natural functions, such as storm protection or nutrient retention. Option value is related to the preference, or willingness to pay, to maintain the possibility of future use. The concept of option value includes preferences for preserving an environmental asset for possible future use by current (philanthropic value) or future generations (bequest value). Nonuse values of wetlands are unrelated to any direct, indirect, or future use, but rather reflect the economic value that can be attached to the mere existence of a wetland (Brander et al. 2006).

Some goods and services derived from wetlands may be traded directly in well-functioning markets and therefore have readily observable values. However, due to market failures resulting from undefined property rights or the (quasi-)public good characteristics of some wetland functions, many valuable wetland services may not be traded directly or even indirectly through markets. The term "public goods" describes services for which beneficiaries cannot be excluded from receiving the service and that the level of consumption by one beneficiary does not reduce the level of service received by another. For example, the reduction in downstream flood risk provided by wetlands in a water catchment is received by the entire population living downstream irrespective of their recognition of the service or the number of other beneficiaries. Due to these characteristics ('non-excludability' and 'non-rivalry' in consumption), markets for such services generally do not exist and the potential for private incentives to sustainably manage wetland services is limited. As a result, wetland ecosystem services are undervalued in decisions regarding the conversion of privately owned wetlands to other productive uses that generate marketable goods and services (e.g., agriculture). The lack of understanding of,

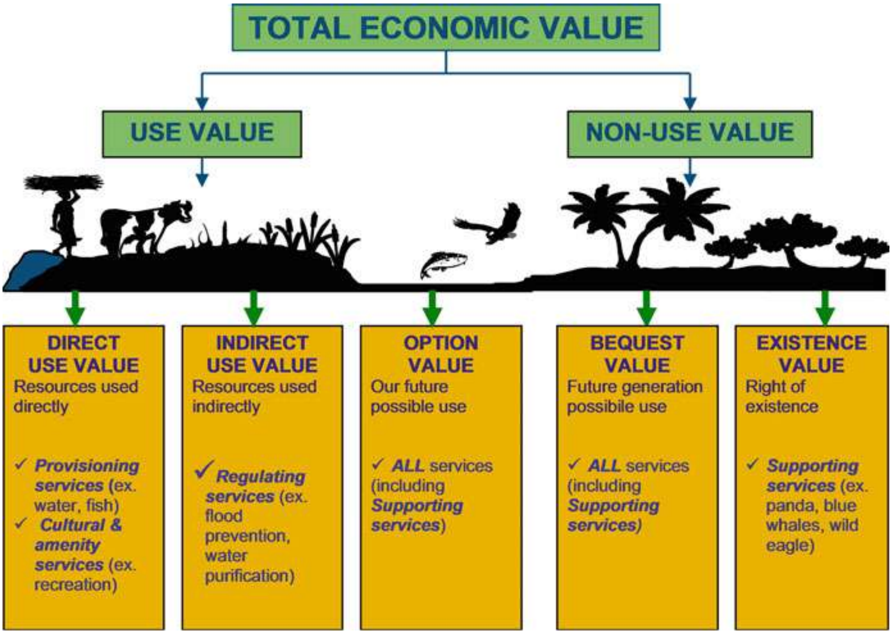

Fig. 2 The Total Economic Value Framework (Adapted from Millennium Ecosystem Assessment (2003), based on a.o. Dixon and Pagiola (1998))

and information on, the value of wetland ecosystem services has also led to their omission in public decisions regarding the conservation of wetlands. Without information on the economic value of wetland services that can be compared directly against the monetary value of alternative public investments, the economic importance of wetlands has tended to be ignored.

In response to this lack of information on the market value of wetland services, there is a large and expanding literature that employs the so-called non-market valuation approaches to estimate the economic value of wetland services. Reviews and meta-analyses of the literature (e.g., by Brouwer et al. 1999; Woodward and Wui 2000; Brander et al. 2006; Ghermandi et al. 2010) show that the estimated values of wetland ecosystem services vary enormously across wetlands with different biophysical and socioeconomic characteristics. Statistical meta-analyses of the literature have attempted to identify factors that help explain this variation to: inform conservation, management, and restoration decisions; enable the prediction of wetland ecosystem service values for policy appraisal or for future scenarios of wetland change; and understand potential trade-offs in the provision and value of wetland ecosystem services.

Based on a large number of case studies, Figure 3 gives an overview of the monetary value of the main services provided by wetlands.

A recent study of 458 value-estimates (De Groot et al. 2012) gives the following (rounded) averages for the Total Economic Value of six main wetland types (on 2007

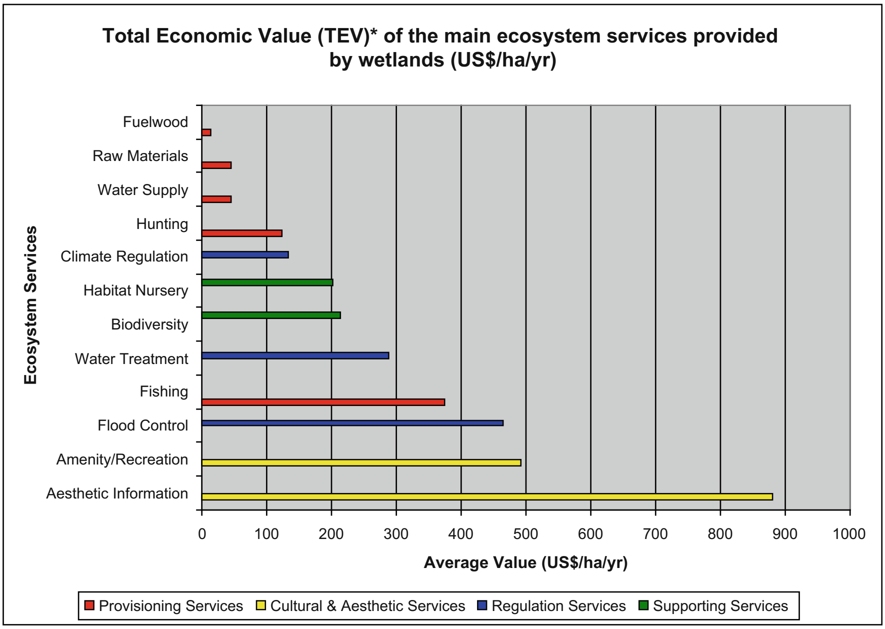

Fig. 3 The Total Economic Value (TEV) of the main ecosystem services provided by wetlands (US$/ha/year). All figures are average global values based on sustainable use levels and taken from two synthesis studies: Schuijt and Brander (2004) (calibrated for 2000), and Costanza et al. (1997) (calibrated for 1994); together covering over 200 case studies (De Groot et al. 2006)

Int.$/ha/year): open ocean 490; coral reefs 350,000; coastal systems (including beaches) 29,000; coastal wetlands (including mangroves) 190,000; inland wetlands 25,000; rivers and lakes 4,300.

Conclusions and Future Prospects

- Following the Millennium Ecosystem Assessment, the Ramsar Convention on Wetlands embraced the concept of ecosystem services and incorporated the benefits obtained by people from wetlands into the Convention's key concept of ecological character.
- The broad classification proposed of ecosystem services by the Millennium Ecosystem Assessment included four categories, namely provisioning (e.g., food, fresh water, wood, and fiber); regulating (e.g., climate, flood and disease regulation, and water purification); supporting (e.g., nutrient cycling, soil formation, and primary production); and cultural (aesthetic, spiritual, educational, and recreational).
- In response to the increasing recognition of ecosystem services, a science-policy platform known as the Intergovernmental Platform on Biodiversity and Ecosystem Services (IPBES) has been established.

- Wetlands provide a broad range of services that are of value to humans. These are the product of ecosystem processes and functions where functions represent the *potential* that ecosystems have to deliver a service which in turn depends on ecological structure and processes. There is not necessarily a one-to-one correspondence between ecosystem functions and services.
- Economic values associated with wetland ecosystem services can be categorized into distinct components of the "total economic value" of wetland natural capital according to the type of use. Direct use values are derived from the uses made of a wetland's resources. Indirect use values are associated with the indirect services provided by a wetland's natural functions, such as storm protection or nutrient retention. Option value is related to the preference, or willingness to pay, to maintain the possibility of future use. Nonuse values of wetlands are unrelated to any direct, indirect, or future use, but rather reflect the economic value that can be attached to the mere existence of a wetland.
- Some goods and services derived from wetlands may be traded directly in well-functioning markets and have readily observable values. However, due to market failures resulting from undefined property rights or the (quasi-)public good characteristics of some wetland functions, many valuable wetland services may not be traded through markets.
- In response to a lack of information on the market value of wetland services, there is a large and expanding literature that employs the so-called non-market valuation approaches to estimate the economic value of wetland services.

The Economics of Ecosystems and Biodiversity (TEEB)

38

C. Max Finlayson

Contents

Abstract

TEEB is a recent initiative that draws attention to the economic benefits of biodiversity globally. Its objective is to highlight the cost of the loss and degradation of biodiversity, including species and ecosystems. The initiative provides information that can help decision-makers recognize and demonstrate the values of biodiversity and support procedures to incorporate these values into decision-making. A report on water and wetlands identified gaps and inconsistencies in knowledge about the economics of water and wetlands as a base for further investigations.

History of TEEB

TEEB is a recent initiative that drew attention to the economic benefits of biodiversity globally. Its objective is to highlight the cost of the loss and degradation of biodiversity, including species and ecosystems. The initiative provides information that can help decision-makers recognize and demonstrate the values of biodiversity and support procedures to incorporate these values into decision-making. The information that follows is largely drawn from the TEEB webpage (http://www.teebweb.org accessed 27 August 2016).

TEEB was developed after a meeting of environment ministers from the G8 + 5 countries in Potsdam, Germany, in March 2007. They agreed to initiate an analysis of the global economic benefit of biological diversity, the costs of the loss of biodiversity, and the failure to take protective measures versus the costs of effective conservation. The German Federal Ministry for the Environment and the European Commission (EC) initiated a global study with the support of an Advisory Board and presented an interim report to the Ninth Conference of the Parties to the Convention on Biological Diversity (CBD COP-9) in Bonn, Germany, in May 2008.

The interim report entitled *The Economics of Ecosystems and Biodiversity* (European Commission 2008) collated evidence and examples of economic valuation, identified elements of a bio diversity valuation framework, and emphasized the importance of issues such as ethics in making choices regarding future values. This report stimulated further interest and the production of a series of reports for specific stakeholders (see below).

The momentum for TEEB has shifted to implementation at the country level in response to requests from governments to build national, regional, and local capacity to produce tailored economic assessments of ecosystems and biodiversity and support to mainstream this information into policy-making. The support provided includes:

- Developing guidance material on how to mainstream the value of ecosystems and biodiversity into decision-making at the country level
- Organizing workshops to build the capacity of national, regional, and local stakeholders to produce tailored economic assessments of ecosystems and biodiversity
- Providing technical expertise to five pilot countries to undertake assessments of their ecosystems and biodiversity and mainstream this information into policy

TEEB comprises a tiered approach for analyzing and structuring valuation through three core principles, namely, that:

- Recognizing value in ecosystems, landscapes, species, and other aspects of biodiversity is a feature of all human societies and communities and is sometimes sufficient to ensure conservation and sustainable use.
- Demonstrating value in economic terms is often useful for policy makers and others to reach decisions that consider the full costs and benefits of an ecosystem

rather than just those costs or values that enter the markets in the form of private goods.
- Capturing value involves the introduction of mechanisms that incorporate the values of ecosystems into decision-making through incentives and price signals.

Major Activities

The TEEB initiative has now presented an impressive number of reports. These include the following reports presented at the Convention on Biological Diversity conference of parties in Japan in October 2010, as listed below:

- TEEB Ecological and Economic Foundations (2010) – the fundamental concepts and state-of-the-art methods for economic valuation of biodiversity and ecosystem services
- TEEB in National and International Policy Making (2010) – an analysis and guidance on how to value and internalize biodiversity and ecosystem values in policy decisions
- TEEB in Local and Regional Policy (2010) – an analysis and guidance for mainstreaming biodiversity and ecosystem values at regional and local levels, with case study examples;
- TEEB in Business and Enterprise (2010) – an analysis and guidance on how business and enterprise can identify and manage their biodiversity and ecosystem risks and opportunities.
- TEEB Synthesis Report (2010) – an introduction to the approaches used and recommendations on how to mainstream the economics of nature into decision-making.

Building on the impetus generated by the initial report, a number of additional studies have been undertaken. These include the following:

- TEEB Manual for Cities (2012) – focuses on how ecosystem services and their valuation can create direct benefits for cities and provides a stepwise guidance on how to do this, with in-depth case studies.
- TEEB Climate Issues Update (2009) – shows how climate change and biodiversity are inextricably linked and how investments in the restoration and conservation of ecosystems can play a major role in combating climate change.
- TEEB Oceans discussion paper (2012) – was presented at the World Oceans Summit, February 2012, and provides guidance on improving ocean management and investing in the economic benefits of marine conservation.
- Nature and its Role in the Green Economy (2012) – a discussion paper prepared for the United Nations Conference on Sustainable Development (Rio + 20) looking at how nature and natural capital contribute to a green economy.

TEEB for Water and Wetlands

This report was initiated by the Ramsar Convention Secretariat with support from the Norwegian, Swiss, and Finnish Governments, and underlines the fundamental importance of wetlands in the water cycle, and presents insights on critical water-related ecosystem services in order to encourage additional policy momentum, business commitment, and investment in the conservation, restoration, and wise use of wetlands (Russi et al. 2013). It uses the TEEB approach to generate a better understanding of the ecosystem service values of water and wetlands and encourages improved decision-making and business commitment for their conservation, investment, and wise use. The main purpose of the report was to identify major gaps and inconsistencies in current knowledge of the economics of water and wetlands, so as to inform agenda-setting for further work on the economics of water and wetlands. The report is accessible from http://www.teebweb.org/wp-content/uploads/2013/04/TEEB_WaterWetlands_Report_2013.pdf (accessed 27 August 2016).

The key messages from the report by Russi et al. (2013) are reproduced below:

1. The "nexus" between water, food, and energy is one of the most fundamental relationships – and increasing challenges – for society.
2. Water security is a major and increasing concern in many parts of the world, including both the availability (including extreme events) and quality of water.
3. Global and local water cycles are strongly dependent on wetlands.
4. Without wetlands, the water cycle, carbon cycle and nutrient cycle would be significantly altered, mostly detrimentally. Yet policies and decisions do not sufficiently take into account these interconnections and interdependencies.
5. Wetlands are solutions to water security because they provide multiple ecosystem services supporting water security as well as offering many other benefits and values to society and the economy.
6. Values of both coastal and inland wetland ecosystem services are typically higher than for other ecosystem types.
7. Wetlands provide natural infrastructure that can help meet a range of policy objectives. Beyond water availability and quality, they are invaluable in supporting climate change mitigation and adaption and support health as well as livelihoods, local development, and poverty eradication.
8. Maintaining and restoring wetlands in many cases also lead to cost savings when compared to manmade infrastructure solutions.
9. Despite their values and despite the potential policy synergies, wetlands have been, and continue to be, lost or degraded. This leads to biodiversity loss – as wetlands are some of the most biodiverse areas in the world, providing essential habitats for many species – and a loss of ecosystem services.
10. Wetland loss can lead to significant losses of human wellbeing and have negative economic impacts on communities, countries, and business, for example, through exacerbating water security problems.

11. Wetlands and water-related ecosystem services need to become an integral part of water management in order to make the transition to a resource efficient, sustainable economy.
12. Action at all levels and by all stakeholders is needed if the opportunities and benefits of working with water and wetlands are to be fully realized and the consequences of continuing wetland loss appreciated and acted upon.

Impact of Human Activities on the Carbon Cycle

39

Hojeong Kang and Inyoung Jang

Contents

Abstract

Human activities have accelerated decomposition in wetland ecosystems, destabilizing carbon stocks in them. In particular, global climate change, drainage and atmospheric deposition are key activities that affect wetland carbon cycle substantially. Global climate change can affect carbon decomposition in wetlands by warming effects as well as more frequent droughts. Elevated CO_2 itself can increase dissolved organic carbon leaching from wetlands through enhanced primary production. For coastal wetlands, sea level rise can also affect carbon mineralization by changes in water chemistry as well as oxygen availability. Wetlands have been subject to drainage for the development of agricultural fields and urban dwellings which can accelerate carbon decomposition by aeration.

https://doi.org/10.1007/978-90-481-9659-3_97

Finally, nitrogen and sulfur deposition can either increase or inhibit carbon decomposition depending on the nutrient status and locations. Overall, human activities can accelerate carbon decomposition in wetlands resulting in greater carbon releases into the atmosphere as CO_2 or CH_4, and into the aquatic ecosystems as DOC.

Keywords

Introduction

The carbon cycle in most wetlands has reached an equilibrium or quasiequilibrium state; however, recent years have witnessed rapid changes in this balance (Yu 2012). In particular, decomposition in many wetlands has been accelerated by human activities, directly or indirectly, thereby destabilizing carbon stocks that had accumulated over geological time scales. This is of great concern as it may result in higher emissions of greenhouse gases (CO_2 or CH_4), thereby exacerbating global climate change. Additionally, the release of greater quantities of dissolved organic carbon (DOC) from wetlands may cause water quality problems or the long-term movement of carbon stocks from inland to marine ecosystems.

Many different activities can affect carbon cycles in wetlands. Three key issues are considered here, namely, global climate change, drainage, and atmospheric deposition.

Global Climate Change

Warming

In general, microbial proliferation and activity are closely and directly correlated with temperature. As such, increase in mean temperature will accelerate soil organic carbon decomposition, thereby releasing greater amounts of CO_2, CH_4, or DOC depending on the edaphic conditions. This effect may be particularly distinct in northern peatlands or wetlands in Artic regions because decomposition in these areas is often limited by low temperature, and the largest increases in temperature are expected to occur at high latitudes in the northern hemisphere. Both experimental studies and longer-term observations have shown that carbon sinks in peatlands or tundra ecosystems may become carbon sources due to global warming (Yu 2012).

Drought

Changes in precipitation due to global climate change are much more complicated than temperature increases, and thus it is difficult to predict how changes in precipitation would affect wetland carbon cycles (Yu 2012). However, more frequent and intensive summer droughts are expected in Europe and Southeastern Asia, which would lower the water levels of wetlands. Such lowering of water levels in wetlands can introduce oxygen into the wetland sediment and accelerate decomposition. Additionally, some wetlands, such as tropical peatlands in Asia, may be exposed to a higher incidence of forest fires. Overall, such changes will destroy previously stable carbon pools in these wetlands (Moore et al. 2013).

Elevated CO_2

Plants use CO_2 as a substrate for photosynthesis, and numerous studies have shown the effects of elevated CO_2 on ecosystems. In wetland ecosystems, the fertilizing effects of CO_2 often do not appear as increases in net primary production of aboveground biomass (i.e., larger plants under elevated CO_2) (Kim and Kang 2008). Instead, activated photosynthesis may result in a greater extent of DOC leaching into water or an increased biomass of plant roots in wetland sediments (Freeman et al. 2004).

Sea Level Rise

The average sea level has increased globally due both to the melting of polar ice and the thermal expansion of the oceans. As sea level rises and flooding in coastal areas becomes more frequent, wetlands located in these areas may experience substantial changes. First, the infiltration of salt water can cause the subsidence of soil layers in coastal wetlands. Second, more salts may interfere with decomposition processes in coastal wetlands. For example, methane-producing wetlands may turn into "sulfate-reducing" wetlands due to a higher supply of sulfate from sea water (Gauci et al. 2004). Further studies are needed to fully explain such issues as the multiple impacts of sea level rise may interact with each other. However, overall results indicate that global climate change would destabilize carbon stocks in wetlands, which may turn into carbon sources in the long term (Yu 2012).

Drainage of Wetlands

Globally, wetlands have historically been subjected to drainage for the development of agricultural fields and urban dwellings. Such drainage is ongoing and increasing in scale. This is particularly serious in developing countries in subtropical or tropical regions where the drainage of wetlands is often used as a means of enhancing crop or biomass production. Recent studies have shown that the construction of ditches to lower water levels has been reported to cause the release of DOC from ancient organic carbon stocks in tropical wetlands (Moore et al. 2013).

Atmospheric Deposition or Fertilization

The atmospheric deposition of sulfur or nitrogen compounds along with the inflow of water containing high concentration of nitrogen (N) and phosphorus (P) fertilizers can have a substantial effect on the carbon cycles in wetlands (Elser et al. 2007). For certain types of wetlands, such as ombrotrophic peatlands, atmospheric input is the only or main source of nutrients, and hence changes in deposition (e.g., decreases in sulfuric acid or increases in inorganic nitrogen) may accelerate the decomposition of organic carbon. This occurs as strong acids, such as sulfuric acid, impede microbial proliferation, whereas nitrogen is typically a limiting nutrient for microbial growth. Marshes located near rivers or estuaries often receive nutrients from nonpoint sources, such as leachates from agricultural fields, and may experience similar consequences. The specific addition of nutrients could increase primary production in wetlands, resulting in increased carbon accumulation in the short term (LeBauer and Treseder 2008).

Ecosystem Services Partnership

40

C. Max Finlayson

Contents

Abstract

The Ecosystem Services Partnership was launched in 2008. It comprises both institutional and individual members. The Partnership has more than 50 organization and more than 400 individual members and comprise the main organizations involved in ecosystem services science, policy, and practice. The governance structure is designed to develop the Partnership and coordinate activities led by active members.

Keywords

Ecosystem services · Partnerships · Networks · Information exchange

History

Information on the Ecosystem Services Partnership (ES-Partnership) is available online at http://www.es-partnership.org/esp (accessed 18 September 2016). The partnership was launched by the Gund Institute for Ecological Economics at the University of Vermont, USA, in 2008, in collaboration with the Environmental

Systems Analysis Group from Wageningen University, the Netherlands, the Institute for Ecological Economics from Portland State University, USA, the Ecosystem Management Department from the University of Kiel, Germany, the Centre of Environmental Management from the University of Nottingham, UK, and the Salento Landscape Ecology Laboratory from the University of Salento, Italy. The Partnership is now coordinated by the Environmental Systems Analysis Group from Wageningen University, the Netherlands, and supported by the Foundation for Sustainable Development in Wageningen, The Netherlands. It comprises both institutional and individual members.

The aims of the Partnership are to enhance communication, coordination, and cooperation, and to build a strong network of individuals and organizations interested in many aspects of ecosystem services. As such it intends to enhance and encourage a diversity of approaches, while reducing unnecessary duplication of effort in the conceptualization and application of ecosystem services. By raising the profile of ecosystem services and promoting better practice, the Partnership will also increase opportunities for financial support and help focus the funding of individual organizations to encourage more efficient use of available resources.

Membership

The Ecosystem Services Partnership is an institutional membership organization with the following governance structure:

- Organizations as well as individuals can become full (paying) members. Core partners are organizations that support or carry out a substantial task or service in line with the aims of the Partnership. A steering committee, elected by full members, has been formed.
- The role of the Steering Committee is to appoint and provide advice to an Executive Committee, as well as make decisions that affect the wider membership. The Steering Committee can comprise a maximum of 30 members.
- The Executive Committee is responsible for the efficient operations of the Partnership. It has 7–9 members including a Chair, Cochair, Secretary, Treasurer, and 3–5 Coordinators.
- A secretariat has been established to support the Steering Committee and Executive Committee and ensure effective communication with the Members and provide support to specifically formed working groups.
- Working Groups have been established to support the development of the science and practice on specific topics and stimulate information exchange and outreach. These are led by active members of the Partnership.

The Partnership currently has more than 50 organization and more than 400 individual members from around the world and comprise the main organizations involved in ecosystem services science, policy, and practice. The above governance structure is designed to develop the Partnership and coordinate activities led by active members.

Conferences

The Partnership encourages discussion and cooperation amongst its members through conferences and workshops. It has held an annual Ecosystem Services Partnership Conference for members to discuss the progress of the Partnership, and developments in ecosystem services science, policy, and practice. From 2016 it will switch to a bi-annual cycle for international conferences, with regional conferences in the in intervening years. It specifically encourages its working groups, national networks, and partnerships to take advantage of the conferences and workshops. It also encourages the involvement of other networks and organizations in the workshops and conferences.

The ninth annual ESP conference was held in Ansan-city, Republic of Korea from 30 May to 3 June 2016. Information on previous conferences available at http://es-partnership.org/esp-conferences/previous-conferences/ (accessed 18 September 2016). In 2016 five Regional Conferences will be organised and will provide a platform for policy makers, practitioners and scientists to connect, exchange ideas, and strengthen the relationship with other networks and partners in the regions.

ESP Working groups

The Ecosystem Services Partnership facilitates the creation of working groups to create a platform for Ecosystem Services science, policy, and practical application. A brief description of existing working groups is provided below.

Biome Expert Groups provide a platform for researchers and practitioners to exchange ideas on Ecosystem Services Assessment in specific biomes (e.g., forests, grasslands, wetlands, etc.) and make the information available to a wider community of users.

Thematic Working Groups enable the creation of a platform for researchers and practitioners to exchange information and ideas on Ecosystem Services Assessment on specific topics, such as indicators, mapping, modeling, valuation, etc.

Regional chapters and national networks focus on the creation of a network on Ecosystem Services Assessment on the national and regional level.

Journals

The journal Ecosystem Services (http://www.journals.elsevier.com/ecosystem-services/ accessed 18 September 2016), published by Elsevier, is officially associated with the ESP. It is an international and interdisciplinary journal that covers the science, policy, and practice of ecosystem services across a number of research disciplines and economic sectors. Papers address the links that occur between (i) ecosystem services and social and economic benefits and associated values; (ii) the levels of ecosystem services and economic, environmental, and land use policies and practices; and (iii) government and business strategies and the sustainability of ecosystem services. Three other journals closely linked to the Partnership include Ecological Indicators (http://www.journals.elsevier.com/ecological-indicators/ accessed 18 September 2016), Solutions (http://www.thesolutionsjournal.com/ accessed 18 September 2016), and The International Journal of Biodiversity Science, Ecosystem Services, and Management (http://www.tandfonline.com/toc/tbsm21/current accessed 18 September 2016).

41 Intergovernmental Panel for Biodiversity and Ecosystem Services (IPBES)

C. Max Finlayson

Contents

Abstract

The Intergovernmental Platform on Biodiversity and Ecosystem Services (IPBES) was established in 2012, as an independent intergovernmental body open to all member countries of the United Nations. It has been developed as the leading intergovernmental body for assessing the state of biodiversity, including its ecosystems and the ecosystem services that provide benefits to people. The structure and purpose of IPBES are described and the work program introduced, including the conceptual framework that has been developed.

Keywords

Ecosystem services · Biodiversity · Intergovernmental agreement

History

The Intergovernmental Platform on Biodiversity and Ecosystem Services (IPBES) was established in April 2012, as an independent intergovernmental body open to all member countries of the United Nations. It is intended to develop IPBES as the leading intergovernmental body for assessing the state of biodiversity, including its ecosystems and the ecosystem services that provide benefits to people (Diaz et al.

2015a, b). Information on the platform and its development is available from http://www.ipbes.net/ accessed 30 August 2016.

Following the completion of the biodiversity and ecosystem services assessment, the Millennium Ecosystem Assessment (www.millenniumassessment.org), there were a number of discussions about developing an ongoing mechanism for assessing the condition of global biodiversity and ecosystem services (Carpenter et al. 2009). This developed further with a consultation process to assess the need and scope of a possible International Mechanism of Scientific Expertise on Biodiversity (IMoSEB) (Loreau et al. 2006; Hoareau and Arico 2010). Following the final meeting of the steering committee for IMoSEB in November 2007, the Executive Director of UNEP was invited, in collaboration with governments and other partners, to convene an intergovernmental and multistakeholder meeting to consider the establishment of an intergovernmental mechanism for biodiversity and ecosystem services.

This led to three intergovernmental and multistakeholders meetings (Malaysia 2008, Kenya 2009, Republic of Korea 2010) to discuss ways to strengthen the science-policy interface on biodiversity and ecosystem services. These meetings identified the gaps and needs for strengthening the science-policy interface and agreed that an IPBES should be established. The last was part of what became known as the Busan Outcome, and was welcomed by the 10th Conference of the Parties to the Convention on Biological Diversity (CBD) in October 2010 and subsequently considered at the 65th session of the United Nations General Assembly (UNGA). This UN Assembly passed a resolution requesting UNEP to convene a plenary meeting to fully operationalize IPBES. The plenary was held in two sessions, the first hosted by UNEP in Nairobi in October 2011 and the second hosted by UNEP in collaboration with UNESCO, FAO, and UNDP, in Panama City in April 2012. The final outcome was that 94 governments adopted a resolution establishing the platform as an independent intergovernmental body.

The Platform

It is intended that IPBES will provide a mechanism for conducting reviews, assessments, and critical evaluations of information and knowledge from multiple sources, including from academic, research organizations, nongovernmental organizations, or community or indigenous organizations. A key component of the processes will be recognition of the role of both the wider scientific and policy communities globally based on establishing credible and transparent processes. In particular, it will endeavor to respond to the needs of Multilateral Environmental Agreements that are related to biodiversity and ecosystem services, including those dealing with wetlands, such as the Ramsar Convention on Wetlands and the Convention on Biological Diversity.

IPBES-1, the first meeting of the Platform's Plenary, was held in Germany in January 2013. The outcomes included decisions on the following: rules of procedure for the Plenary of the Platform, next steps for the development of the initial IPBES work program, procedure for receiving and prioritizing requests put to the platform, IPBES administrative and institutional arrangements, and status of contribution and initial budget for the platform for 2013.

Arrangements were made for intersessional activities and the establishment of a Multidisciplinary Expert Panel to oversee the development of the initial work program. The Multidisciplinary Expert Panel is required to develop its own working methods with the support of the secretariat and to retain its independence and focus on scientific and technical issues. Vohland et al. (2011) emphasized the necessity for IPBES to be seen as credible and effective with challenges including setting the agenda for technical assessments, organizing the assessment process, and making the findings more policy relevant.

IPBES-2, the second meeting of the Platform's Plenary, was held in Turkey in December 2013. The outcomes included decisions on the following: the work program for 2014–2018, including the related scoping documents, institutional arrangements for implementing the work program, communication and stakeholder engagement, guidance on strategic partnerships, consideration of the budget for the implementation of the work program, and a conceptual framework. The meeting adopted a very ambitious initial work program for the platform for the next 5 years and demonstrated a strong commitment to its implementation by pledging more than half (US$ 25.4 million) of the total US$ 43.5 million required, in what will be remembered as the "Antalya consensus."

IPBES currently has 125 government members and is administered by UNEP under the auspices of UNEP, FAO, UNDP and UNESCO. The IPBES secretariat is hosted by the German government on the UN campus, in Bonn, Germany. The decision making body of IPBES is the IPBES Plenary that comprises government members and observers, with two subsidiary bodies, the Bureau which is responsible for administrative activities, and the Multidisciplinary Expert Panel that is responsible for the technical and scientific work program. The work program consists of objectives, deliverables, actions, and milestones for the four core functions of Capacity Building, Knowledge Generation Catalysis, Assessment, and policy support. Scientists from around the world contribute on a voluntary basis to the work of IPBES. Peer review is used to ensure high scientific standards are achieved in the work program and that a range of views is incorporated. IPBES has also made a concerted effort to attract social researchers, including from sociology, economics, geography, political science and others, to join the IPBES program to complement the work undertaken by experts from the natural sciences (Larigauderie et al. 2015).

Diaz et al. (2015a, b) report on the development of a conceptual framework that designed to bring the IPBES effort together to ensure integration of the knowledge and biodiversity interface for biodiversity, and to accommodate diverse views on biodiversity while stimulating new thinking and approaches. The framework built on the Millennium Ecosystem Assessment and further emphasized the role of institutions as sources of environmental problems and solutions. It also extended the valuation of the contribution of nature to the quality of human life to include monetary to spiritual values. It also explicitly incorporated multiple knowledge systems. The conceptual framework is shown in Fig. 1.

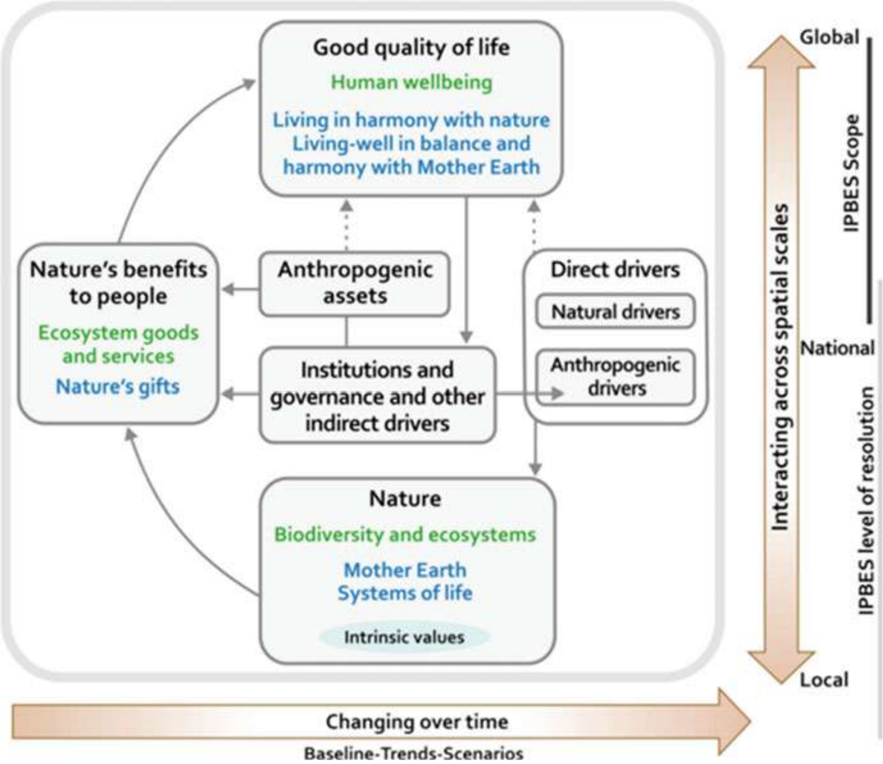

Fig. 1 IPBES conceptual framework (from IPBES http://www.ipbes.net/conceptual-framework)

The IPBES workplan was implemented from 2014 with a set of assessments and capacity building activities (Gilbert 2014). The initial assessments considered pollination and pollinators associated with food production (IPBES 2016a), and scenarios analysis and modeling of biodiversity and ecosystem services (IPBES 2016b). Others are planned.

Millennium Ecosystem Assessment

42

C. Max Finlayson

Contents

Abstract

The Millennium Ecosystem Assessment (MA) was initiated in 2001 with the objective being to assess the consequences of ecosystem change for human wellbeing and the scientific basis for action needed to enhance the conservation and sustainable use of those systems. The outcomes were presented in five technical volumes and six synthesis reports. The combined outputs provided a state-of-the-art appraisal of the condition and trends of the world's ecosystems and the services they provide for people as well as an analysis of the options to restore, conserve, or enhance the sustainable use of ecosystems.

https://doi.org/10.1007/978-90-481-9659-3_81

basis for action needed to enhance the conservation and sustainable use of those systems. It involved more than 1,360 biophysical and social scientists worldwide with the outcomes presented in five technical volumes and six synthesis reports. The combined outputs provided a state-of-the-art appraisal of the condition and trends of the world's ecosystems and the services they provide for people as well as an analysis of the options to restore, conserve, or enhance the sustainable use of ecosystems. The information that is presented below is taken from the overview of the MA and its outcomes provided at http://www.millenniumassessment.org/en/Index-2.html (accessed 27 August 2016).

The main activities of the MA occurred between 2001 and 2005 having officially started in April 2001 and being formally launched by UN Secretary–General Kofi Annan, on World Environment Day, 5 June 2001. The first year was primarily concerned with designing the approaches that would be used for the global and subglobal assessments; this information was presented as a framework for undertaking the assessment (MA 2003). The core assessment and drafting of the technical reports was carried out in the second and third years. The draft reports went through two rounds of governmental and peer review with the findings being formally approved by the Board on 23 March 2005.

The key "users" of the MA were represented through a Board and included representatives of the Convention on Biological Diversity, Convention to Combat Desertification, the Ramsar Convention on Wetlands, and the UN Convention on Migratory Species, as well as national governments, United Nations agencies, civil society, including indigenous peoples, and the private sector. Other members were also added to ensure appropriate geographical and sectoral distribution among Board members. UNEP provided the overall coordination and employed the MA Director who was based at the WorldFish Centre in Malaysia. The overall budget was approximately US$24 million including around $7 million through in-kind contributions for subglobal assessments.

The assessment was undertaken by an international network of scientists and other experts, with a process based on that used for the Intergovernmental Panel on Climate Change. More than 1,300 authors from 95 countries were involved and organized into four working groups. Three of these groups – Condition and Trends, Scenarios, and Responses – carried out the global assessment component with the fourth undertaking a set of subglobal assessments.

Main Findings

The main findings were presented in four volumes covering current status and trends, scenarios, policy responses, and multiscale assessments. The general synthesis report presented the main findings of the MA (MA 2005a). These are presented below and accessible at http://www.millenniumassessment.org/documents/document.356.aspx.pdf (accessed 27 August 2016).

- Over the past 50 years, humans have changed ecosystems more rapidly and extensively than in any comparable period of time in human history, largely to

meet rapidly growing demands for food, fresh water, timber, fiber, and fuel. This has resulted in a substantial and largely irreversible loss in the diversity of life on Earth.
- The changes that have been made to ecosystems have contributed to substantial net gains in human wellbeing and economic development, but these gains have been achieved at growing costs in the form of the degradation of many ecosystem services, increased risks of nonlinear changes, and the exacerbation of poverty for some groups of people. These problems, unless addressed, will substantially diminish the benefits that future generations obtain from ecosystems.
- The degradation of ecosystem services could grow significantly worse during the first half of this century and is a barrier to achieving the Millennium Development Goals.
- The challenge of reversing the degradation of ecosystems while meeting increasing demands for services can be partially met under some scenarios considered by the MA, but will involve significant changes in policies, institutions, and practices that are not currently under way. Many options exist to conserve or enhance specific ecosystem services in ways that reduce negative trade-offs or that provide positive synergies with other ecosystem services.

The main conclusion from the MA findings is that "human actions are depleting the Earth's natural capital and putting such strain on the environment that the ability of the planet's ecosystems to sustain future generations can no longer be taken for granted."

Wetland Findings

The water and wetland synthesis was developed, in part, to inform the Ramsar Convention on Wetlands about the findings of the MA. This was published in 2005 (MA 2005b) and presented to the Conference of Parties of the Convention later that year.

The main findings from the wetland synthesis were summarized as a number of key points, as shown below.

- Wetland ecosystems (including lakes, rivers, marshes, and coastal regions to a depth of 6 meters at low tide) are estimated to cover more than 1,280 million hectares, an area 33% larger than the United States and 50% larger than Brazil. However, this estimate is known to underrepresent many wetland types, and further data are required for some geographic regions. More than 50% of specific types of wetlands in parts of North America, Europe, Australia, and New Zealand were destroyed during the twentieth century and many others in many parts of the world degraded.
- Wetlands deliver a wide range of ecosystem services that contribute to human wellbeing, such as fish and fiber, water supply, water purification, climate

regulation, flood regulation, coastal protection, recreational opportunities, and, increasingly, tourism.

- When both the marketed and nonmarketed economic benefits of wetlands are included, the total economic value of unconverted wetlands is often greater than that of converted wetlands.
- A priority when making decisions that directly or indirectly influence wetlands is to ensure that information about the full range of benefits and values provided by different wetland ecosystem services is considered.
- The degradation and loss of wetlands is more rapid than that of other ecosystems. Similarly, the status of both freshwater and coastal wetland species is deteriorating faster than those of other ecosystems.
- The primary indirect drivers of degradation and loss of inland and coastal wetlands have been population growth and increasing economic development. The primary direct drivers of degradation and loss include infrastructure development, land conversion, water withdrawal, eutrophication and pollution, overharvesting and overexploitation, and the introduction of invasive alien species.
- Global climate change is expected to exacerbate the loss and degradation of many wetlands and the loss or decline of their species and to increase the incidence of vector-borne and waterborne diseases in many regions. Excessive nutrient loading is expected to become a growing threat to rivers, lakes, marshes, coastal zones, and coral reefs.
- Growing pressures from multiple direct drivers increase the likelihood of potentially abrupt changes in wetland ecosystems, which can be large in magnitude and difficult, expensive, or impossible to reverse.
- The projected continued loss and degradation of wetlands will reduce the capacity of wetlands to mitigate impacts and result in further reduction in human wellbeing (including an increase in the prevalence of disease), especially for poorer people in lower-income countries, where technological solutions are not as readily available. At the same time, demand for many of these services (such as denitrification and flood and storm protection) will increase.
- Physical and economic water scarcity and limited or reduced access to water will be major challenges for society and are likely to be key factors limiting economic development in many countries. However, many water resource developments undertaken to increase access to water have not given adequate consideration to harmful trade-offs with other services provided by wetlands.
- Cross-sectoral and ecosystem-based approaches to wetland management – such as river (or lake or aquifer) basin-scale management, and integrated coastal zone management – that consider the trade-offs between different wetland ecosystem services are more likely to ensure sustainable development than many existing sectoral approaches and are critical in designing actions in support of the Millennium Development Goals.
- Many of the responses designed with a primary focus on wetlands and water resources will not be sustainable or sufficient unless other indirect and direct drivers of change are addressed. These include actions to eliminate production subsidies, sustainably intensify agriculture, slow climate change, slow nutrient loading,

correct market failures, encourage stakeholder participation, and increase transparency and accountability of government and private-sector decision-making.

- Major policy decisions in the next decades will have to address trade-offs among current uses of wetland resources and between current and future uses. Particularly important trade-offs involve those between agricultural production and water quality, land use and biodiversity, water use and aquatic biodiversity, and current water use for irrigation and future agricultural production.
- The adverse effects of climate change, such as sea level rise, coral bleaching, and changes in hydrology and in the temperature of water bodies, will lead to a reduction in the services provided by wetlands. Removing the existing pressures on wetlands and improving their resiliency is the most effective method of coping with the adverse effects of climate change. Conserving, maintaining, or rehabilitating wetland ecosystems can be a viable element to an overall climate change mitigation strategy.
- The MA conceptual framework for ecosystems and human wellbeing provides a framework that supports the promotion and delivery of the Ramsar Convention's "wise use" concept. This enables the existing guidance provided by the Convention for the wise use of all wetlands to be expressed within the context of human wellbeing and poverty alleviation.

The outcomes of the MA were welcomed by the Convention through Resolution IX.1 Annex A (http://www.ramsar.org/pdf/res/key_res_ix_01_annexa_e.pdf, accessed 16 September 2013), and the guidelines for wise use of wetlands mapped onto the MA conceptual framework to illustrate the breadth of existing guidelines and gaps (Finlayson et al. 2011).

Biological Adaptations

Kevin J. Stevens

Anatomy of Wetland Plants

43

James L. Seago

Contents

Abstract

Plants that inhabit wetlands range from very tiny plants to large trees and display various structural adaptations to wet areas. Most plants retain an epidermis that in roots may produce hairs and are one to several cell layers thick. Large air spaces (aerenchyma) are often found in the cortex and/or pith of stems and roots and the bark of some plants. Aerenchyma begins as small spaces between cells and then progresses through one of the three developmental paths: schizogeny, lysigeny, and expansigeny. In roots, the aerenchyma is delimited by an inner barrier (endodermis) and an outer barrier (hypodermis). Modifications to these layers may include Casparian bands, suberin lamellae, or secondary cell wall development. In roots, vascular tissues may be comprised of a single xylem element or multiple strands of alternating xylem and phloem. In stems, vascular tissues may be found in ring(s), as scattered bundles or with root-like configurations.

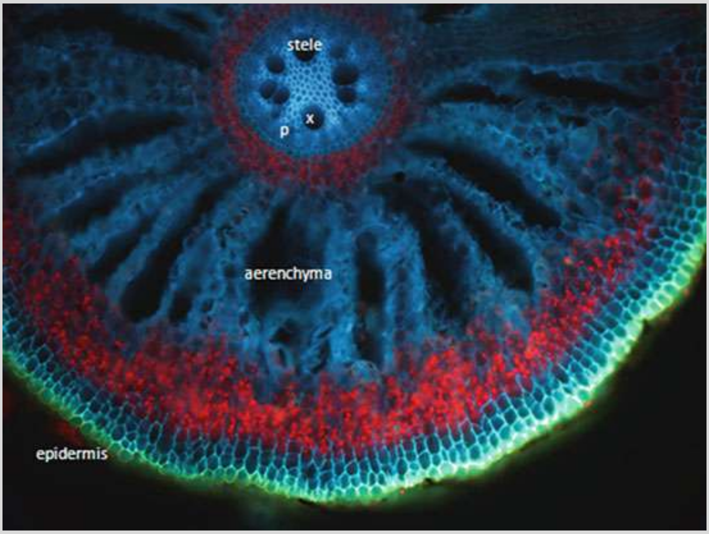
Definitions

Anatomy of a wetland plant root:

In a root cross section, three tissue systems are evident. The outermost layer of cells, the epidermis, makes up the dermal tissue system. Internal to the dermal tissue system is the cortex. Cells in the cortex comprise the ground tissue system. The ground tissue largely consists of parenchyma cells. The innermost layer of cortical cells, the endodermis, have modifications called Casparian bands, which help limit the movement of solutes and water through the roots. The outermost layer of cortical cells may also possess Casparian bands, which in this case is called exodermis. If these cortical cells lack Casparian bands, the region is called the hypodermis. While most roots and stems have gaps or intercellular spaces between cortical cells that allow gas movement, in many wetland plants these spaces or lacunae are large and parenchyma cells containing these spaces are referred to as aerenchyma. Internal to the endodermis is a central cylinder or stele where vascular tissues (xylem and phloem) are found. Xylem is involved in the transport of water, nutrients, and plant-derived compounds up the plant while the phloem is involved in the transport of plant-derived compounds down the plant. In dicotyledonous plants, the xylem radiates out from the center of the stele forming arms or poles. Phloem is found between the poles. Species with two poles have a diarch xylem arrangement. Those species with three poles have a triarch arrangement and more than three poles are called polyarch. Monocot roots are similar; however, the xylem does not extend to the center of the stele. Monocot roots have a central pith of parenchyma cells. Below is a cross section of a cat-tail (*Typha latifolia*) root, viewed using fluorescence microscopy.



Introduction

It might seem surprising, but flowering plants that inhabit wetland habitats, including aquatic habitats of ponds and streams, are extremely varied in their structural adaptations to these watery places. These species range in size from extremely tiny plants such as *Trithuria filamentosa* (Hydatellaceae), a member of a small group once classified as a grass but now included in the water lilies as a Basal Angiosperm, to Eudicot tree species of southern US swamps, e.g., *Nyssa aquatica* (Nyssaceae) and the very widespread Monocot, cat-tail, *Typha glauca* (Typhaceae).

Among the Basal Angiosperms, the water lilies (e.g., *Nymphaea*, Nymphaeaceae; *Cabomba caroliniana*, Cabombaceae) are all wetland/aquatic species. Many Monocot families of flowering plants have wetland or aquatic species – from the Acoraceae (*Acorus calamus*) through the Amaryllidaceae (*Leucojum aestivum*) to the Poaceae (e.g., *Oryza sativa*). We tend to find more Monocot species than Eudicot species characteristic of wetlands, and these are herbaceous annuals to perennials. The wetland Eudicots range from some Ranunculaceae (*Ranunculus repens*), through the Gunneraceae (*Gunnera magellanica*) of the Core Eudicots, to the Menyanthaceae (*Nymphoides cristata*) and are usually herbaceous. Anatomical features like epidermis, cortex, and stele originate from apical meristems and are characterized as follows.

Epidermis

Most wetland species retain their epidermis throughout their lives (see Fig. 3, courtesy of Aleš Soukup). The roots of aquatic species often have particular adapations for the aquatic environment such as hairs. However, some species do not have hairs, and these have a thick hypodermis. These species lose their epidermis, and the exodermis, the specialized layer(s) of the hypodermis, becomes the outermost zone of the roots; thus, there are no root hairs. The occurrence of cutins in the epidermis of the stems and roots of aquatic species has been recorded, but in recent years diffuse suberin has been found in the root epidermis, thus making it even more of a barrier layer, especially to fungal infection (Meyer and Peterson 2013).

Cortex: Aerenchyma

While are no typical wetland plant anatomies, some anatomical adaptations are common to many wetland plants. One of the most common adaptations of many plants which inhabit wetland/aquatic environments is the occurrence of sizeable air spaces which are known as aerenchyma and almost always occur in the cortex or ground tissue of organs. In some species, expanded spaces or cavities can be found in the pith of roots or pith and ground tissue of stems.

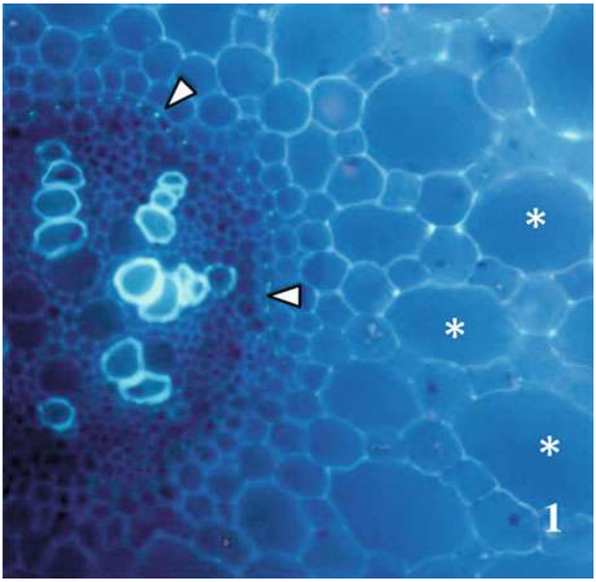


Fig. 1 Cross section of a *Victoria amazonica* root. Expansigenous aerenchyma (*). Endodermis with Casparian bands (*arrowheads*)

The term, aerenchyma (Schenck 1890), is used to represent the organized air space tissue of roots, stems, and leaves. All types of aerenchyma arise from very small intercellular spaces which themselves develop by schizogeny or separation of cell walls at the intersections of cells, usually where the cells arise from meristems. Further expansion of these tiny spaces into lacunae (the enlarged air spaces of aerenchyma) occurs in three main ways, developmental paths which have only recently been well elucidated by Seago et al. (2005), who applied the terminology to roots, and confirmed by Jung et al. (2008), who expanded the concepts to include stems. The ways in which the living cells of aerenchyma can be packaged have been documented for many species by Justin and Armstrong (1987).

Expansigeny is the development of aerenchyma from these tiny spaces by means of cell divisions of the surrounding cells and by concomitant cell enlargement or elongation of the cell walls along the developing space in such a way that neither cell separations nor cell deaths contribute to the enlarged air spaces. Examples are especially common in the water lilies (Fig. 1, e.g., *Victoria amazonica* in the Nymphaeales).

Schizogenous aerenchyma develops after the initial intercellular space formation and only by the separation (or schizogeny) of adjoining cell walls, and the resulting schizogenous space forms a lacuna (Fig. 2, *Justicia americana*, Acanthaceae). Examples can be found in many Monocots and Eudicots.

In lysigeny, aerenchyma arises primarily by the death of specific cells to create an enlarged space; these cell deaths are usually accompanied by some schizogenous separations early in their formation. The developmental patterns which produce this lysigeny are clearly constitutive in many wetland plant species (Jung et al. 2008).

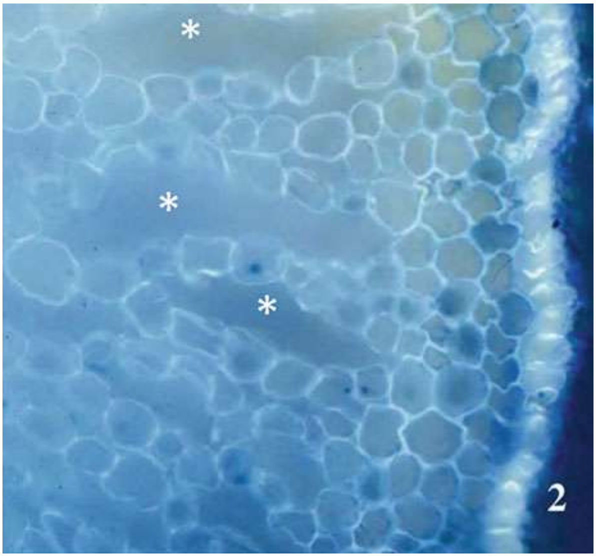

Fig. 2 Cross section of a *Justicia americana* root. Schizogenous aerenchyma (*)

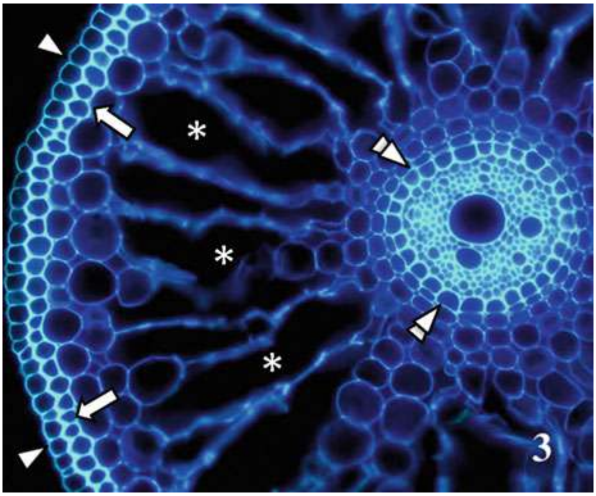

Fig. 3 Cross section of a *Glyceria maxima* root. Lysigenous aerenchyma (*). Epidermis (*arrowhead)*, exodermis (*arrow*), endodermis (*double arrowhead*). Note the central polyarch stele

Oryza sativa is one of the best known examples of lysigeny (Fig. 3). If some schizogeny also occurs in lacunar formation, we term the aerenchyma schizo-lysigenous (Fig. 4, *Phragmites australis*, Poaceae).

In stems and petioles of many species, e.g., *Cabomba caroliniana*, a Basal Angiosperm in the Nymphaeales, aerenchyma organization is often much like that in roots, but enlarged cavities, even in the pith, are also common, especially in the grasses.

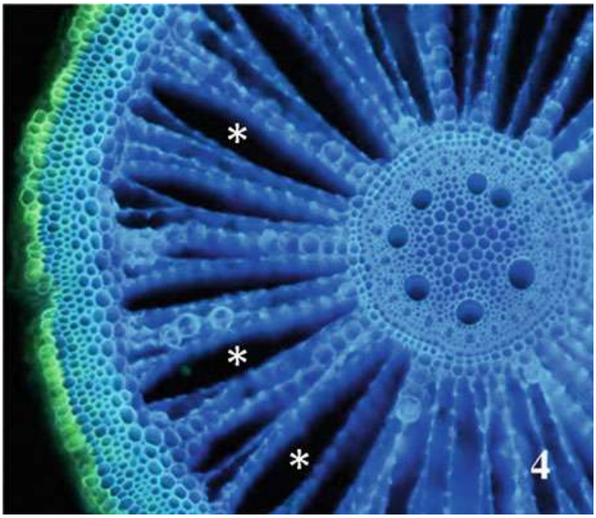

Fig. 4 Cross section of a *Phragmites australis* root. Schizo-lysigenous aerenchyma (*). Note the central polyarch stele

Cortex: Barrier Layers

In roots, aerenchyma is delimited by two barrier layers (Enstone et al. 2003). The endodermis with Casparian bands represents the innermost barrier layer (Fig. 1), while the hypodermis forms the outermost barrier layer. The hypodermis is a distinct, concentric layer or layers of cells interior to the epidermis that is derived from the meristem and that is often modified into an exodermis, a layer like the endodermis with Casparian bands, plus suberin lamellae. An endodermis is a characteristic of the innermost layer of the root cortex in all flowering plants (Fig. 5, *Nymphoides cristata*), but it can also be found in stems of some wetland plants – from emergents like *Typha* to floating plants like *Najas* (Hydrocharitaceae; Fig. 6).

In the wetland Basal Angiosperms, there is always an endodermis with Casparian bands, but a few species also have suberin lamellae. Most species, especially Eudicots, have a simple endodermis with Casparian bands only (Fig. 5, *Nymphoides cristata*); however, many species, especially Monocots, have suberin lamellae and secondary lignified walls added to Casparian bands (Fig. 7, *Iris pseudacorus*, Iridaceae). An exodermis, the hypodermis with Casparian bands and suberin lamellae in the cell walls, can be found in many wetland species, especially Monocots, all wetland Basal Angiosperms, e.g., *Nymphaea odorata*, and a few Eudicots, even including stems, e.g., *Nymphoides peltata* (Fig. 8).

An exodermis can be found in rhizomatous plants such as cattails and can be several cell layers thick (Fig. 9, *Typha glauca*), each cell having Casparian bands, suberin lamellae, and secondarily lignified cell walls. The nature of these cell wall modifications in the barrier layers and epidermis has been summarized by Enstone et al. (2003) and Meyer and Peterson (2013).

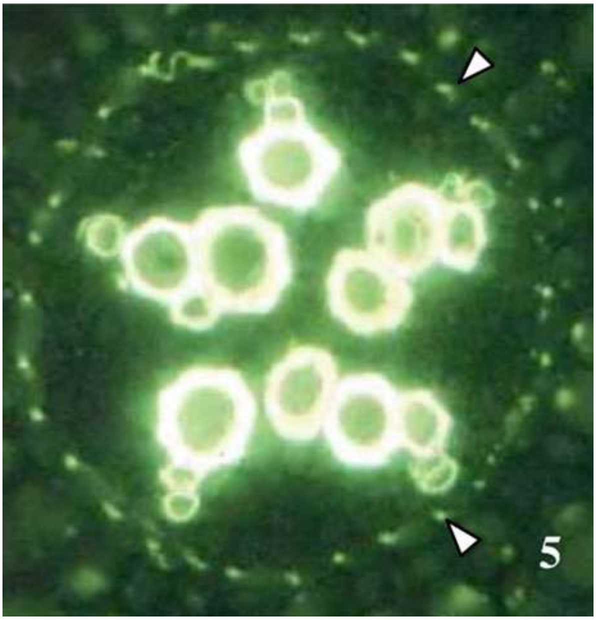

Fig. 6 Cross section of a *Najas minor* stem with endodermis (*arrowhead*) and a simple stele

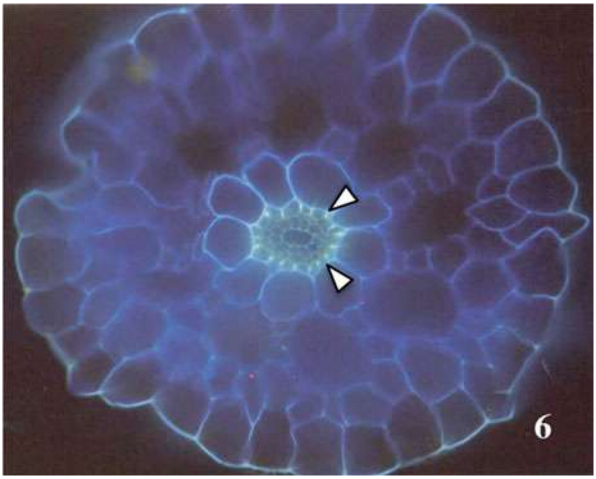

Vascular Tissues

The primary vascular tissue, or stele, in roots is a product of the root apical meristem. Basal Angiosperms have a very wide variety of arrangements of their root primary xylem and phloem, varying from one xylem element to a polyarch condition,

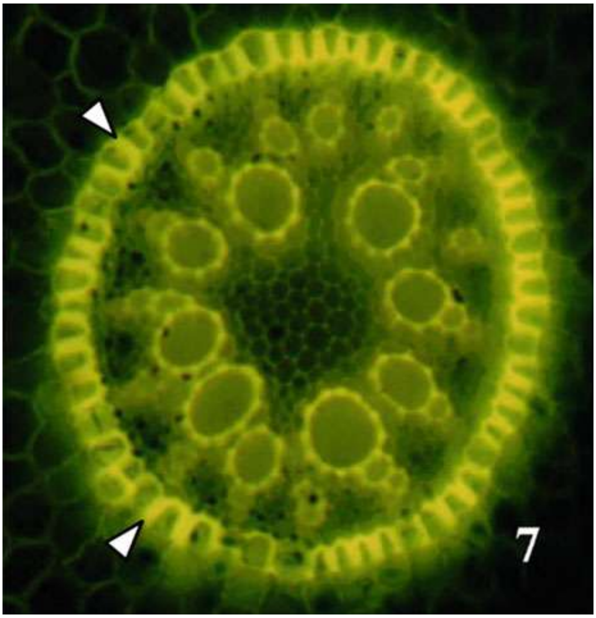

Fig. 7 Cross section of an *Iris pseudacorus* root. In addition to Casparian bands the endodermis has been further modified by the deposition of suberin lamellae, and lignified secondary walls (*arrowhead*). Note the central polyarch stele

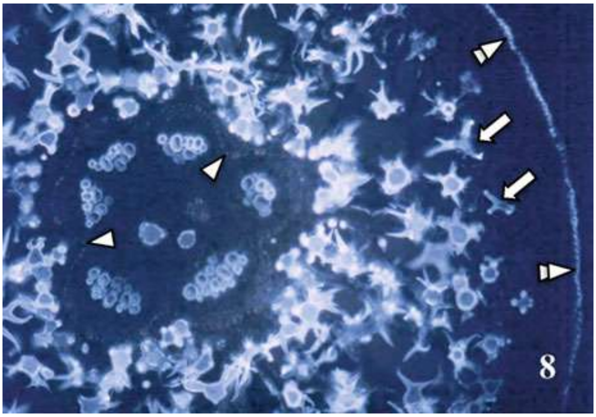

Fig. 8 Cross section of a *Nymphoides peltata* stem with endodermis (*arrowheads*) around the stele and an exodermis with suberin lamellae (*double arrowheads*). Note the presence of astrosclereids (*arrows*) throughout the cortex

whereas Monocots and Eudicots generally differ from each other in conspicuous ways (see Seago and Fernando 2013). Eudicots are usually depicted as having 2 –6 poles or strands of alternating xylem and phloem (termed diarch to hexarch, respectively; e.g., Fig. 5, pentarch in *Nymphoides*), while Monocots typically have 6 or more such poles (hexarch to polyarch, often 10–20 poles; see Figs. 3, 4, 7, 10 – *Typha glauca*). However, there are some notable exceptions, even within a genus;

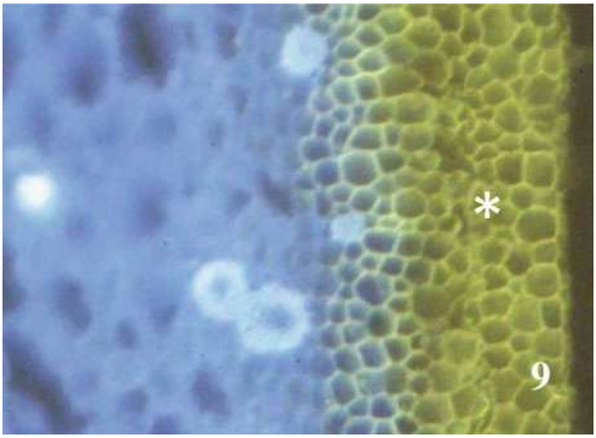

Fig. 9 Cross section of a *Typha glauca* rhizome showing a multiseriate exodermis (*)

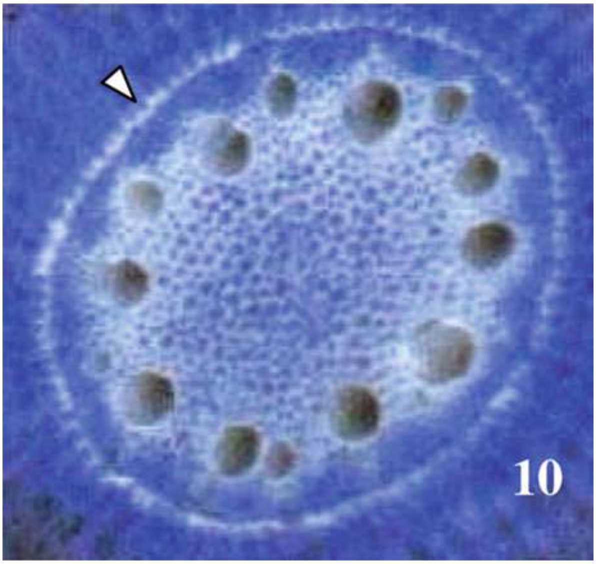

Fig. 10 Cross section of a *Typha glauca* root. Note the endodermis (*arrowhead*), and polyarch stele

some species of the basal core Eudicot, *Gunnera*, have polyarch arrangements of primary xylem and phloem without secondary growth (Fig. 11), but other species are tetrarch with secondary growth. Species with more than 6 strands of xylem and phloem usually do not undergo secondary growth in their roots.

In stems, Eudicots generally have one ring of vascular bundles (xylem and phloem, an arrangement which can allow for secondary growth), and Monocots have two, more or less, concentric rings of vascular bundles or vascular bundles

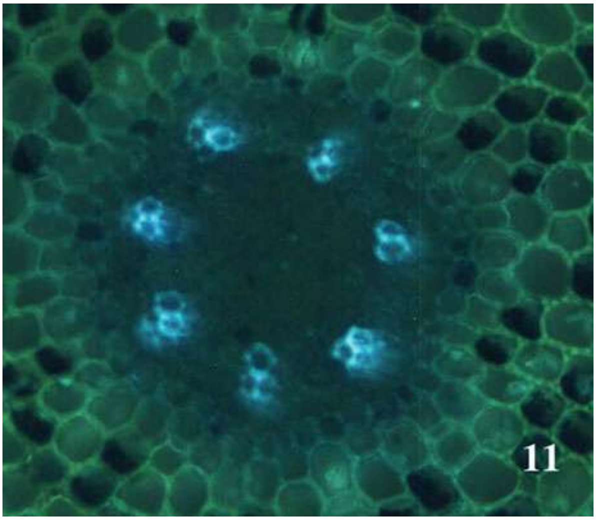

Fig. 11 Cross section of *Gunnera magellanica* root. *G. magellanica* is a eudicot with polyarch stele (7 xylem and phloem poles)

scattered throughout the ground tissue of the stem. However, some species with very small stems have structural configurations and cell types resembling those of roots. For example, the water lilies (Nymphaeaceae, Cabombaceae, Hydatellaceae) have stems with a stele surrounded by an endodermis. Some species of Monocots, like the river-dwelling *Najas*, have very small steles with little vascular tissue, plus an endodermis with Casparian bands and aerenchyma (Fig. 6). Far larger emergent plants, like *Typha*, have large rhizomes with an endodermis separating a central cylinder of scattered vascular bundles and a cortex with vascular bundles. Among Eudicots, some of the wetland plants, e.g., *Gunnera magellanica*, *Trapa natans* – Lythraceae, and *Nymphoides peltata*, have stems with an endodermis surrounding the entire stele (Fig. 8) or all vascular bundles (e.g., *Justicia americana*, not shown).

Petioles of wetland plants ordinarily have some aerenchyma, but they do not usually have an endodermis delimiting the ground tissue from the vascular bundles. One exception to this is the genus *Gunnera* (Fig. 12) in which most species have a constitutive endodermis with Casparian bands in lower portions of petioles, even when they are above water levels.

Secondary Tissues: Aerenchymatous Phellem

Arenchymatous tissue is not found in secondary xylem or phloem but can be found in periderm (outer bark) in which the phellem, or outer bark, is modified into aerenchyma. This has been well documented in North America in the well-known invasive species, *Lythrum salicaria* (Lythraceae; Stevens, et al. 2002). Here, cell division and cell expansion lead to the enormous lacunae of the phellem.

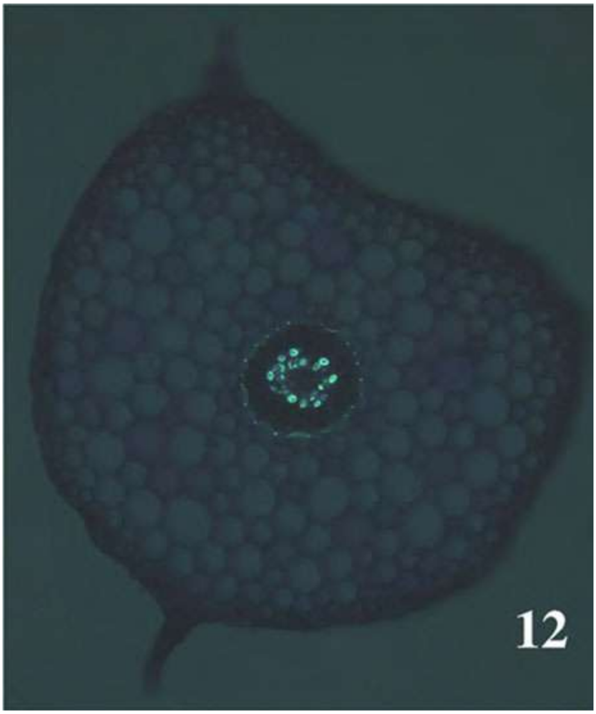

Fig. 12 Cross section obtained from midway along a *Gunnera flavida* petiole. Note the endodermis with Casparian bands around the vascular bundle

Future Challenges

Relatively few plant species that inhabit wetland or aquatic environments have actually been examined well enough for scientists to know their structural features; thus, many more species, especially from bog habitats which are woefully underexamined, should be investigated. Much progress has been made on the ways in which the plant parts under the surface of the water get aerated, but the structural connections among the different plant organs to facilitate this gaseous exchange are not well known.

Abstract

Anaerobic conditions cause death in plants grown in saturated soils. Where flooding is predictable, species may time germination to coincide with low water levels. In other areas, specialized adaptations, such as rapid shoot elongation, adventitious root production, or shoot buttressing and fluting, are strategies to counteract oxygen depletion. Aerenchyma in shoots and roots allow oxygen to move from emergent to submerged organs and may diffuse out of roots oxidizing

surrounding soils. Temperature gradients drive pressurized air movement within some plants. Shallow, extensive, intertwining roots can improve oxygen penetration and provide a belowground network, limiting hurricane damage. Prop roots and pneumatophores enhance oxygen movement in some mangrove plants. Floating mats are produced in areas experiencing subsidence. Solute imbalances can create conditions where water leaves the cytoplasm. Water loss can be prevented by production of salt barriers and nontoxic solutes in saline conditions, but also by confining CO_2 production to night time.

Roots out of soil in wetland plants:

While roots are generally thought of as growing down, underneath the shoot, this is not always the case. Many flooded plants will produce roots along submerged parts of the stem. These roots are referred to as adventitious roots (a). Adventitious root development can occur rapidly following submergence. Adventitious roots may assume the role of the root system if the original root system perishes and their location in the water column allows them access to more oxygen rich waters. The capacity to develop roots on stems permits the ready propagation of wetland plants in commercial nurseries. Some plants produce upward growing roots called pneumatophores (b). The roots are believed to function like snorkels providing a means of transferring oxygen to submerged plant parts. Several types of pneumatophores, differing in their developmental patterns, are recognized. In addition to pneumatophores, some mangrove plants produce stilt roots. These are downward growing roots forming on the trunk or lower branches that anchor in the substrate and provide additional support to emergent shoots (Photos by Kevin Stevens).

Introduction

The vast majority of plant species on Earth cannot survive long in water-saturated soils, not because of the water itself but because the soils are anaerobic. Oxygen diffuses into water 10,000 times slower than air. Therefore, saturated, or *hydric*, soils become anaerobic quickly, and without oxygen as the terminal electron acceptor in the electron transport chain, aerobic metabolism ceases in plant roots. Under anoxic conditions, terrestrial plants, and some wetland plants, will begin metabolizing through fermentation, whose end product (ethanol) is toxic and generally cause death within 24 h. Many wetland plants actually accelerate rates of fermentation to maintain adequate levels of ATP but release the ethanol to the environment and thus do not accumulate this toxic byproduct. An additional stress triggered by anaerobic hydric soils involves production of other toxic byproducts, as specialized microbes are able to substitute other electron acceptors in the electron transport chain, which become toxic when reduced, such as sulfate reduction to lethal hydrogen sulfide. Many species of wetland plants have evolved shoot and root adaptations that enable delivery of oxygen to the roots, avoiding the problems caused by anaerobic soils. In areas where the timing of flood events is predictable, many species have evolved timing mechanisms enabling seeds to germinate during draw down conditions.

Coastal wetlands experience the additional stress of salt water and have evolved adaptations to either exclude salt from entering the roots, sequester, or secrete it. These mechanisms involve preventing entry of salt at the root soil interface, producing nontoxic organic solutes to compensate for osmotic imbalance, packing the salt into vacuoles, xylem tissue, or old leaf tissue, or some species may excrete salts via salt glands.

Anaerobic Avoidance Strategies

General strategies used to avoid anaerobic metabolism include (1) shoot elongation to render a portion of the plant out of the water, (2) production of adventitious roots along the aerobic portions of the stem, (3) slowing or shutting down metabolism until floodwaters retreat, (4) buttressing or fluting of the basal shoot to increase surface area exchange, and (5) specialized root adaptations (see below).

Aerenchyma

The most ubiquitous adaptation enabling shoots to deliver oxygen to the roots is the creation of air spaces called *aerenchyma*. When the surrounding environment becomes hypoxic, the hormone ethylene is produced, which triggers production of the enzyme cellulase. This enzyme breaks down cellulose within both shoots and roots, creating honeycomb or snorkel-like air spaces. These airspaces allow oxygen to diffuse into the roots and from the roots to the pore space lining of surrounding soils to create an *oxidized rhizosphere*. In the oxidized rhizosphere, reduced toxic substances, such as ammonia and hydrogen sulfide, become oxidized into nontoxic nitrate and sulfate, respectively. Aerenchymous tissue may occupy up to 60% of a wetland plant's root tissue volume (Mitsch and Gosselink 2007).

Root Adaptations

Root adaptations that enable aerobic metabolism include shallow but extensive rooting, *prop root* formation, and *pneumatophore* or air root production. In general, forested wetland tree species kill off their taproots when young and send shallow lateral roots far beyond their drip line. In addition to enhancing oxygen penetration, these extensive lateral roots form a tapestry with one another, rendering such species as baldcypress (*Taxodium distichum*) and water tupelo (*Nyssa aquatica*) highly resistant to hurricane damage; when basal areas reach greater than 30 m^2 ha^{-1}, these two canopy species also keep readily wind-thrown midstory and herbaceous vegetation intact (Shaffer et al. 2009).

To enhance oxygen penetration to the roots, red mangroves (*Rhizophora* spp.) develop aboveground roots called prop roots. These roots are densely topped with spongy air-filled lenticels that allow oxygen diffusion into the roots.

Black mangrove (*Avicennia* spp.) similarly contain thousands of pneumatophores, which are spongy extensions of the main roots (about 30 cm long), which climb vertically through the mud and are exposed during low tides. Both prop roots and pneumatophores greatly enhance root oxygenation, as demonstrated by experiments that blocked airflow using substances such as Vaseline®. This has not been demonstrated in the vertical root extensions, or *knees,* of baldcypress; it does appear, however, that the knees offer structural support during tropical storm events (Conner et al. 2012).

Perhaps the most intriguing root adaptation to chronic flooding is the development of floating marsh or *floatant*. The world's large delta complexes undergo cycles of progradation and degradation as their rivers periodically switch paths. As a newly forming delta progrades, the abandoned delta subsides as its sediments compact and dewater. This subsidence leads to increased flood durations and at some point the vegetative community must "sink or swim." Vegetative species that form floatant create gaseous roots and rhizomes such that the entire root mat detaches from the subsoil and essentially becomes a hydroponic marsh (Sasser et al. 1991). While these floating marshes can be very healthy ecosystems, they do not stand up to the strong winds of tropical storms. In high winds and strong storm surge, the floatant marshes roll up in carpet-like fashion and get thrown landward where they strand and die.

Thermo-Pressurized Gas Flow

Thermo-pressurized gas flow is a mechanism used by plants to actively move oxygen from shoots to roots. To achieve this, plants use the temperature and water pressure differentials between the exterior ambient air and the internal cortical tissue to create pressure gradients, which push oxygen through aerenchymous shoots into aerenchymous roots. Pressures generated during daytime peak temperatures are up to 30 times higher than those generated at night (Brix et al. 1992). Originally, humidity was thought to be the driving force in pressurized gas flow (Brix et al. 1992). However, this process can occur in trees even when the plant is dormant, so humidity is not likely to be the driving force. First discovered by Dacey (1980, 1981) in water lilies (*Nuphar luteum*), thermo-pressurized flow was once thought to be unique; however, it has since been demonstrated in several other hydrophyte (Brix et al. 1992) and wetland tree species (Grosse and Schroder 1984; Grosse et al. 1992). The route for gaseous transport may differ among species. *Alnus glutinosa*, for example, uses meristematic tissue in lenticels for pressurized gas flow, rather than leaf tissue. This pathway, however, is 8× less efficient than gas flow through leaf aerenchyma. Nevertheless, pressurized gas flow in mature trees occurs only when the tree is dormant, but in seedlings it occurs in leaves, before the seedling establishes aerenchyma (Mitsch and Gosselink 2007).

Adaptations to Salt

In general, wetland vascular plants are faced with the same challenges as single celled organisms when the outside aqueous environment has more solutes than inside the cell. The water potential of the outside solution is lower and water escapes the cytoplasm. A suite of wetland species have solved the problem by (1) eliminating salt (NaCl) at the root surface to maintain nearly fresh internal solutions, (2) increasing nontoxic organic compounds inside the cytoplasm to reverse osmotic imbalance, (3) isolating or eliminating salt that enters through the roots, and (4) using a photosynthetic pathway that minimizes fresh water requirements.

Salt Barriers

Mangroves of the genera *Sonneratia*, *Rhizophora*, and *Laguncularia* have tight membranes on the root surface that reduce the salinity of internal water to 1–1.5 ppt compared to 35 ppt of the outside sea water (Mitsch and Gosselink 2007). The mangrove *Avicennia* spp. is also able to greatly reduce the salinity internally but only to about 10% of sea water.

Organic Solutes

To prevent salt from becoming toxic internally, some wetland plant species produce nontoxic organic compounds to more than match the osmotic potential of the outside aqueous solution. These compounds are called *osmotica* and include prolene and beta glycine.

Salt Elimination

At the cellular level, vacuoles can serve as trash cans for sodium chloride. Salt also can be packed into old leaf tissue and the leaves excised. More elaborate mechanisms include the salt glands on the leaves of *Spartina* spp., which actively secrete sodium ions relative to potassium. Remarkably, baldcypress packs salt into last year's dead xylem tissue. Baldcypress, which live over 1,000 years, can therefore be used to reconstruct historic tropical storm events (Hupp and Morris 1990).

C_4 Photosynthetic Pathway

Wetland plants inhabiting saline environs face much the same "physiological drought" (Schimper 1903) problems as plants in arid environments; in both cases plants are rooted in a substrate with very low water potential, because of either dryness or high salt content. The dilemna from a water loss perspective is that vascular plants lose water by opening their stomata to capture carbon dioxide for carbon fixation in the photosynthetic process. Water is a much smaller molecule than carbon dioxide, so it readily diffuses out of open stomata. Water loss through evapotranspiration must be compensated by water uptake through the roots. An additional problem for species that rely exclusively on the C_3 pathway involves the wasteful fixing of oxygen rather than carbon dioxide, a process known as *photorespiration*. C_3 plants obtain the CO_2 needed for the initial steps in photosynthesis during daylight hours. Photorespiration occurs because the initial enzyme in the C_3 pathway, known as Rubisco (ribulose biphosphate carboxylase), has a relatively low affinity for carbon dioxide and also fixes oxygen to the 3-carbon sugar glycophosphate. Vascular plants with the additional C_4 pathway solve the problem by initially fixing carbon dioxide at night. Fixation occurs via the enzyme PEP (phosphoenol pyruvate) carboxylase, which has a very high affinity for CO_2. Wetland plant species that use the C_4 pathway are far more efficient with water use per amount of carbon fixed.

William Armstrong and Timothy D. Colmer

Contents

Abstract

Low gas-diffusivity and oxygen-solubility in water are primary constraints in wetland and aquatic environments. Consequentially, microbes may remove oxygen from all but surface layers of waterlogged soils and generate phytotoxins, while shoot-submergence may substantially reduce CO_2-availability for photosynthesis, compromising carbohydrate production. Oxygen limitations may cause energy crises within the plant and self-generation of damaging reactive oxygen species; enhanced generation and entrapment of the gaseous hormone ethylene also accompany waterlogging and submergence. Globally, wetlands differ in altitude, timing, duration and depth of flooding, light, temperature, and biogeochemistry. Consequently, suites of adaptive traits have evolved in plants to accommodate these varied conditions. Adaptations include anoxia avoidance by facilitating gas

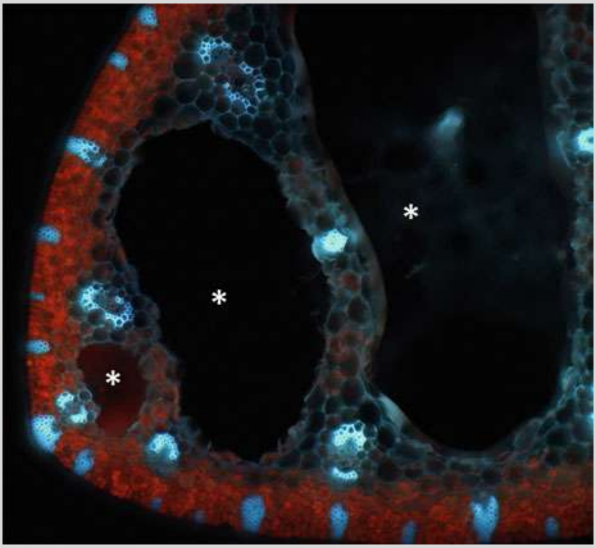
Definitions

Breathing underwater:

Plants, like animals, require oxygen for respiration. Usually, this is obtained from the air. Plant organs below the ground, roots and sometimes stems, obtain oxygen from air in spaces between soil particles. As water levels rise, the air spaces become filled with water and oxygen becomes limited. Many plants, however, possess an internal pathway for the exchange of gases between submerged and nonsubmerged tissues. This pathway consists of spaces that are interconnected forming a continuous pathway for the flow of gases between leaves, stems, and roots. The most pronounced spaces, clearly evident in cross sections, are referred to as aerenchyma. Oxygen moves down this pathway to submerged tissues, while carbon dioxide and other gases move from the submerged tissues out through the stems and leaves. The following image shows aerenchyma in the leaf of cat-tail (*Typha latifolia*). A cross section of a leaf was obtained by hand and viewed using a fluorescence microscope (Photomicrograph by Kevin Stevens).



Introduction

Impeded gas exchange is a primary constraint for plants in wetland and aquatic environments. Excess water can interrupt O_2 supply for respiration causing "energy crises" and when shoots are submerged restrict CO_2 supply for photosynthesis with adverse effects on the carbohydrate economy. Other major constraints include soil-generated phytotoxins and self-generated reactive oxygen species (ROS).

Waterlogging robs the soil of much of its gas-filled space. Together with low O_2 solubility in water, very low liquid-phase diffusivities, and microbial activities, this causes *flooded soils* to become *very O_2 deficient, high in CO_2, and reservoirs of potential phytotoxins* (see also Vol. 1, ▶ Chap. 31, "Microbially Mediated Chemical Transformations in Wetlands"); free O_2 is limited to surface layers (Armstrong 1979). Unless roots and other buried organs can exploit these layers, obtain O_2 from/via an emergent shoot/root (the snorkel effect) (Armstrong 1979; Vartapetian et al. 2008; Colmer and Voesenek 2009), or become quiescent and/or utilize anaerobic metabolism until the soil drains, death is inevitable (Vartapetian et al. 2008; Bailey-Serres and Voesenek 2008; Colmer and Voesenek 2009). Even re-exposure to O_2 may be damaging unless cells are able to remove ROS that are often generated (Blokhina et al. 2003; Vartapetian et al. 2008).

Whole or partial submergence of shoots further impedes gas-exchange; although CO_2 is highly soluble in water, its availability for underwater photosynthesis is limited by an even lower diffusivity than that of O_2 (Armstrong 1979) and (for most plants which can only utilize CO_2) by its progressive transformation to bicarbonate and carbonate with increasing pH (Maberly and Madsen 2002). Submergence also hinders photosynthetic O_2 escape, raising internal $[O_2]$:$[CO_2]$ ratios, which can enhance photorespiration and reduce any net photosynthesis (Colmer et al. 2011). However at night, CO_2 can accumulate, particularly in roots, to levels that might impede metabolism (Greenway et al. 2006). With submergence, production of the gaseous phytohormone ethylene (C_2H_4) may be stimulated by lower internal O_2 concentrations and its escape hindered by its very low solubility in water (Colmer and Voesenek 2009). Depending upon the species, C_2H_4 accumulation can have a variety of physiological consequences, some favorable, e.g., induction of lysigenous aerenchyma and new adventitious roots (Colmer and Voesenek 2009), and some unfavorable, e.g., premature senescence in submerged shoots.

Since wetlands occur worldwide and at most altitudes, the types of flooding regime vary enormously in seasonality, duration, water depth, light, temperature, and biogeochemistry. The selection pressures imposed by such variety of regime have led to the evolution of suites of adaptive traits in plants that fit various flooding scenarios. Adaptations include: (i) those directed to minimizing development of anoxia in tissues viz. "anoxia avoidance" by (a) facilitating gas-exchange with the atmosphere to support aerobic metabolism (Armstrong 1979; Colmer and Voesenek 2009), (b) a total submergence escape strategy (Bailey-Serres and Voesenek 2008; Colmer and Voesenek 2009), (c) a medium term submergence tolerance strategy involving a nonelongation response (termed "quiescence" (Bailey-Serres and

Voesenek 2008; Colmer and Voesenek 2009) to reflect restricted elongation and reduced carbohydrate consumption, although the tissues do remain metabolically active), and (d) leaves capable of photosynthesis when submerged (Colmer et al. 2011; Maberly and Madsen 2002); (ii) anoxia tolerance: short or long term (Gibbs and Greenway 2003; Greenway and Gibbs 2003); and (iii) protection from ROS (Blokhina et al. 2003; Vartapetian et al. 2008) and phytotoxins (Armstrong 1979; Colmer and Voesenek 2009; Watanabe et al. 2013). Each broad category of adaptation involves several contributing traits. Key traits relating to the principal flooding regimes are set out in Table 1 and commented upon below.

Anoxia Avoidance

Soil flooding only. Here, the major source of O_2 for most rhizomes and roots is internal gas-phase diffusion from/via the shoot, and despite daytime photosynthesis, the source concentration usually differs little from day to night at *circa* 21% (Armstrong 1979). Root tips are particularly sensitive to anoxia, but since their growth is O_2 dependent and in waterlogged soils supported by internal transport from shoots, roots of wetland species may rarely experience total tissue anoxia. The length of root (and rhizome) growth in anoxic soils depends upon: (i) their internal (chiefly cortical) gas-space provision and (ii) O_2 "consumption" along the root by respiration in the cells and radial O_2 loss (ROL) from the root – ROL is influenced by microbial and chemical O_2 demands in the soil and root anatomy and morphology (Armstrong 1979).

Root aerenchyma (see also Vol. 1, ► Chap. 43, "Anatomy of Wetland Plants") is pivotal to the success of most wetland species; it lowers respiratory demand per unit volume and, even more importantly, reduces substantially the resistance to long distance diffusion (Armstrong 1979). Where aerenchyma formation involves lysis, the cell death is thought to be caused by reactive oxygen species (ROS), with production triggered by endogenously produced ethylene. Cells that remain alive may owe their survival to ROS scavengers such as metallothionins and/or phytoglobins (Yamauchi et al. 2011; Mira et al. 2016). Roots of many wetland species also have a "tight" suberized sub-apical O_2-conserving exodermal barrier to ROL (Armstrong 1979; Armstrong et al. 2000; Colmer and Voesenek 2009; Watanabe et al. 2013) that also impedes phytotoxin entry, although some nutrient and water uptake can still proceed. Most nonwetland species form relatively small amounts of cortical aerenchyma, and some cannot form it (Justin and Armstrong 1987). In species without aerenchyma, the fractional porosity (FP; gas volume/organ volume) remains low ($\leq$5%) and respiratory demand relatively high; the interaction of this porosity and respiratory demand is strongly synergistic and limiting to adequate root aeration. Figure 1 demonstrates the benefits of aerenchyma formation, which conveys a high FP (15–60%), lower diffusive resistance, and lower O_2 demand to the plant. The superior aeration of wetland root types is dependent upon, in order of importance, reduced diffusive resistance > reduced respiratory

Table 1 Overview of the hypothesized importance of various traits associated with plant tolerance of soil waterlogging and/or submergence, for five contrasting types of wet environments inhabited by some terrestrial plant species (Reproduced, with a few modifications, from Colmer and Voesenek (2009), Functional Plant Biology, with permission of CSIRO Publishing. After Colmer and Voesenek (2009))

Aquatic leaf traits (biophysical)	NA	NA	NA	***	***
Leaf gas films	NA	NA	***	***	**
Convective gas movement	*	***	NA	***	NA

Short duration = < 1 week. Prolonged duration = > 1 week, typically > 4 weeks
Shallow = < 1 m (i.e., water levels that plants are capable of "outgrowing")
Deep = > 1 m, typically a few meters or more
* = of little importance; ** = of moderate importance; *** = of high importance; −ve* = costs out-weigh benefits – such a response can decrease fitness in the specific environment; NA = not applicable; superscript (a) represents Isoetids that have weak barrier formation facilitating entry of sediment CO_2 for internal diffusion via lacunae to the leaves for photosynthesis
Note: True aquatic species often display biochemical leaf traits for enhanced underwater photosynthesis Only biophysical leaf traits are considered here, as our focus is on terrestrial species
ROL radial oxygen loss, *ROS* reactive oxygen species

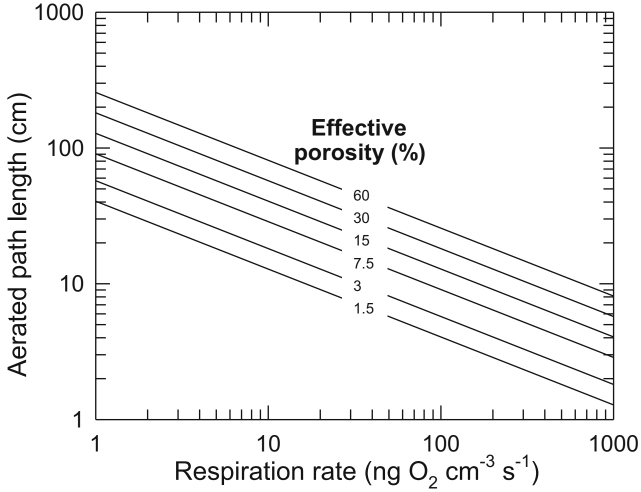

Fig. 1 Predicted lengths (aerated path length) to which roots might grow in waterlogged soil at 20 °C supported only by internal O_2 diffusion from the shoot. Based on the equation $C_o = ML^2/2D_e\varepsilon\tau$, (Armstrong 1979), where C_o is the source pO_2 (*ca* 270×10^{-6} g cm^{-3}); M, the respiration rate; L, the maximum aerated path length; D_o the O_2 diffusion coefficient (0.201 cm^2 s^{-1}); ε, the fractional porosity (FP) ; τ, a tortuosity factor. Respiratory demand and porosity were assumed to be uniform along the diffusion path, tortuosity (=1) and no ROL. Also a zero order reaction for O_2 consumption vs. internal pO_2 was assumed since O_2 consumption at the cellular level is unaffected by [O_2] down to very low levels (≤1 kPa)

demand > reduced ROL (Armstrong 1979). Species with highest root FP are usually the deepest rooting (Justin and Armstrong 1987).

Rice root growth and respiration decline when the O_2 partial pressure [pO_2] in the cortical gas-space near the apex approaches 2 kPa. Other species (not just wetland) behave similarly (Armstrong and Beckett 2011), but it is unclear at what internal pO_2 growth stops or where in the root the critical point might be. However, this pO_2 is likely to be close to zero and in nonporous meristematic tissue. The apex and stele are least likely to receive an optimal O_2 supply (Armstrong et al. 1994) and the first tissues where anaerobic metabolism will be required. However, wetland species generally have narrow steles that help minimize the O_2 deficit that can develop radially across them (Armstrong et al. 2000). Since *root growth* is *O_2-dependant* and stops at some very low value before anoxia can become pervasive, this is, in a sense, *an anoxia avoidance strategy*; localized anoxia/severe hypoxia may not be lethal. Anaerobic metabolism in stele or meristem may result in ethanol leakage into the cortex where it can be aerobically catabolized.

In some wetland species, air is driven through the rhizomes by daytime pressure flows (convections) from emergent leaves/shoots, while at night diffusion predominates (Armstrong et al. 1992; Brix et al. 1992). Aerobic conditions prevail internally during the day but localized hypoxia/anoxia may develop at night. Even in species without convective flows, e.g., *submerged* rice, diurnal changes in O_2 supply from

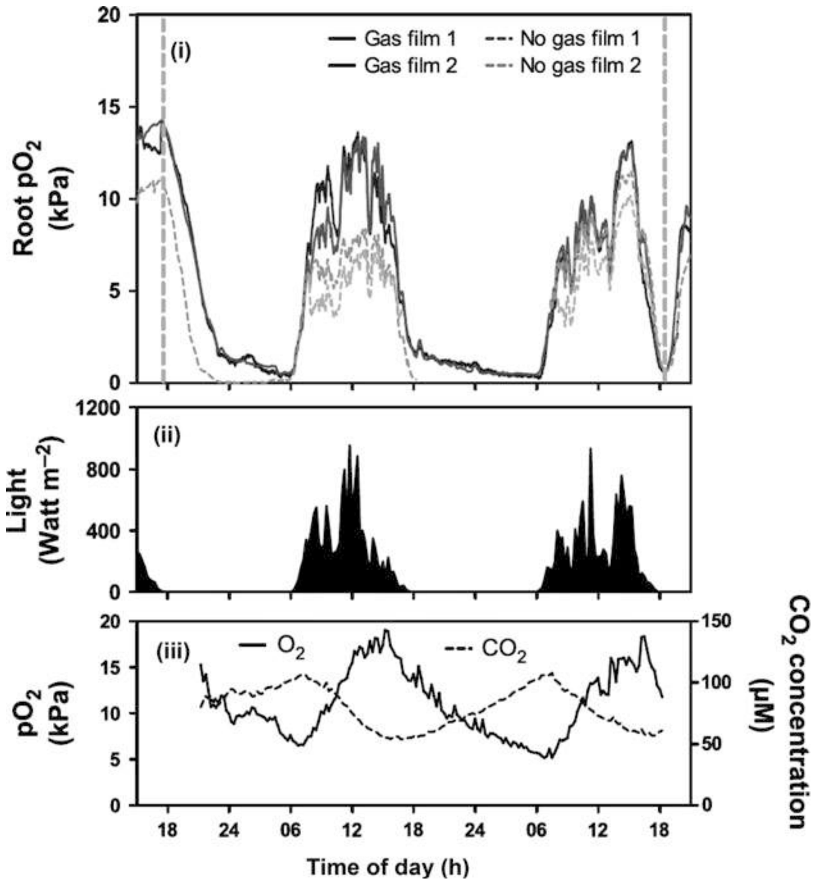

Fig. 2 Partial pressures of O_2 (pO_2) in roots of rice (*Oryza sativa*) and floodwater O_2 and CO_2 during a complete 2-d submergence event in a bunded paddy field. (i) Adventitious root pO_2 was measured using O_2 microelectrodes inserted ca. 200 μm into the root, 10 mm below the root–shoot junction, in two plants with intact leaf gas films (*solid lines*) and in two plants in which the gas films had been removed by brushing with 0.01% Triton X-100 just before submergence (*gray dashed lines*); *vertical dashed lines* represent submergence/de-submergence. Roots were buried in the anoxic soil with the root–shoot junction ca. 4 cm below the soil surface, so that O_2 entered roots from the shoot via aerenchyma. Only intermittent data are available during the night for plants without leaf gas films (i.e., no data visible in the recordings of O_2 shown in part (i) when it was below detection). Water depth varied from 48 to 50 cm above the soil during submergence. (ii) Surface light was measured ca. 440 m from the bunded field using a weather station. (iii) Floodwater pO_2 (iii; *solid line*) was measured using a Clark-type O_2 electrode; floodwater CO_2 (iii; *dashed line*) was calculated from the pH, temperature, and electrical conductivity (Reproduced from Winkel et al. (2013), New Phytologist, with permission from John Wiley and Sons)

photosynthesis (Fig. 2) (Winkel et al. 2013) can result in root growth stopping at night and resuming at first light (Waters et al. 1989). A short-term requirement for anaerobic metabolism then complements the over-riding strategy of anoxia avoidance via internal O_2 transport (Waters et al. 1989).

Shoot submergence: the low O_2 escape syndrome (LOES) and other traits. LOES-type plants have the ability to emerge above floodwaters re-establishing gas-phase continuity between buried/submerged organs and the atmosphere (Bailey-Serres and Voesenek 2008). In *Rumex palustris*, petioles re-orientate upwards and subsequently elongate, both processes being stimulated by entrapment of the endogenously produced plant hormone ethylene, and a signal cascade involving other hormones and processes modulating petiole growth (Voesenek et al. 2006). In deepwater rice, endogenous ethylene together with gibberellic acid (GA) is involved in rapid (e.g., 25 cm/day) internode and leaf sheath extension to raise foliage above the water surface during long-duration floods. Free-floating aerenchymatous adventitious roots emerge from the submerged nodes. These roots might replace the original basal system (malfunctioning because of O_2 deficiency/ phytotoxins) and can be photosynthetically competent, contributing at least to their own respiratory substrate needs (Colmer and Voesenek 2009). Free-floating roots are common to several wetland species.

Many rain-fed rice varieties of moderate stature respond to ethylene with some elongation but cannot outgrow their submergence. When waters recede, the elongated shoot collapses due to water deficits and/or ROS damage (Blokhina et al. 2003; Bailey-Serres and Voesenek 2008; Colmer and Voesenek 2009). However, a few rice land races that do *not* elongate are tolerant of short-term complete submergence endowed by: an insensitivity to ethylene with substrates conserved by a lack of shoot extension, a slow down of leaf senescence, down-regulation of other nonessential processes, induction of anaerobic energy production in tissues that become anoxic, and upregulation of ROS defenses to avoid damage upon O_2 re-entry (Bailey-Serres and Voesenek 2008). ROS defense might also be needed to cope with large diurnal O_2 fluctuations in submerged plants. Although roots might experience some anoxia/ severe hypoxia during nights, shoot tissues continue to have access to O_2 via leaf gas films at night and from photosynthesis when light is available.

Gas films on leaves and leaf sheaths of some submerged and partially submerged plants are an aid to anoxia-avoidance. If in contact with the atmosphere, gas films aid O_2 transport from the atmosphere (Beckett et al. 1988). Where submergence is total, and leaves cutinized, gas films reduce resistance to CO_2 entry from the water via the stomata and facilitate underwater photosynthesis; these films also reduce resistance for O_2 entry at night, e.g., submerged rice (Winkel et al. 2013). The beneficial role of gas films on leaves of terrestrial wetland plants is highlighted in Colmer et al. (2011) and Winkel et al. (2013).

Photosynthesis under water. Morphological and anatomical leaf traits that reduce resistance to gas-exchange when submerged, as well as biochemical traits collectively termed carbon-concentrating mechanisms, enhance underwater photosynthesis (Maberly and Madsen 2002). Specific examples include: (i) leaves that lack or have a reduced cuticle so facilitating inward diffusion of bicarbonate (HCO_3^-), CO_2, and O_2 to/from the water, e.g., underwater water-lily and *Rumex palustris* leaves (Colmer and Voesenek 2009; Voesenek et al. 2006) and (ii) crassulacean acid metabolism (CAM)-type metabolism for night time fixation of CO_2 (e.g., *Isoetes* sp.) (Maberly and Madsen 2002). In addition, plants may use sediment CO_2 for photosynthesis when completely submerged, the major CO_2 source in some species such as *Lobelia dortmanna* (Pedersen et al. 1995).

Tolerance of Anoxia

True quiescence is central to prolonged anoxia tolerance. Few plant organs (some seeds, over-wintering rhizomes and turions) survive prolonged total anoxia, living in a kind of anaerobic retreat. Bud extension can also occur anaerobically in only some species – a switch from quiescence to shoot growth and LOES (Colmer and Voesenek 2009).

Prerequisites for long-term survival of anoxia are: (i) the control of energy metabolism (i.e., production and consumption) under O_2 deprivation and (ii) the presence of considerable carbohydrate reserves (Brandle and Crawford 1987). The former involves changes in transcription and thus transcript abundances of certain genes and translational regulation also of synthesis of proteins; this altered state may be induced by a sensing of energy depletion (or resulting changes, e.g., lowered cytoplasmic pH) or as recently suggested directly by O_2 deficiency (Gibbs et al. 2011; Licausi et al. 2011), but it is uncertain at what internal O_2 concentration this occurs. The suggestion, however, that some plant species/tissues might downregulate respiration in response to declining O_2 supply even at relatively high concentrations has been challenged (Gibbs and Greenway 2003; Armstrong and Beckett 2011) as the interpretations had not taken into consideration the existence of O_2 gradients created by diffusive resistance and O_2 consumption in tissues of low porosity, leading to "anoxic cores." Gibbs and Greenway (2003) concluded that high anoxia tolerance must be to a large extent associated with directing the sparse energy produced under anoxia to processes crucial to survival and only in some strategic organs to growth. Maintenance of transmembrane gradients is crucial, otherwise compartmentation between cytoplasm and vacuole will fail and death will ensue. Metabolic differences between anoxia tolerant and intolerant tissues are set out in Fig. 3.

Wetland plant rhizomes are exposed to long periods of anoxia as the result of autumnal dying down of foliage and loss of gas-phase connection to the atmosphere. Prior to this, carbohydrates, mostly starch, constitute up to 50% of rhizome dry weight. Downregulation of metabolism conserves these carbohydrates for sustaining maintenance processes during anoxia, for supporting renewed growth in the spring, and for processing ROS scavenging molecules on re-exposure to O_2 (Colmer and Voesenek 2009).

Reactive Oxygen Species (ROS) and Post-anoxic Injury

Excessive formation of ROS (e.g., superoxide radicals, hydroxyl radicals, hydrogen peroxide, singlet oxygen) during low O_2 conditions and upon re-aeration is common amongst plants (Blokhina et al. 2003; Vartapetian et al. 2008; Colmer and Voesenek 2009). An important source of superoxides is the mitochondria, and superoxide can

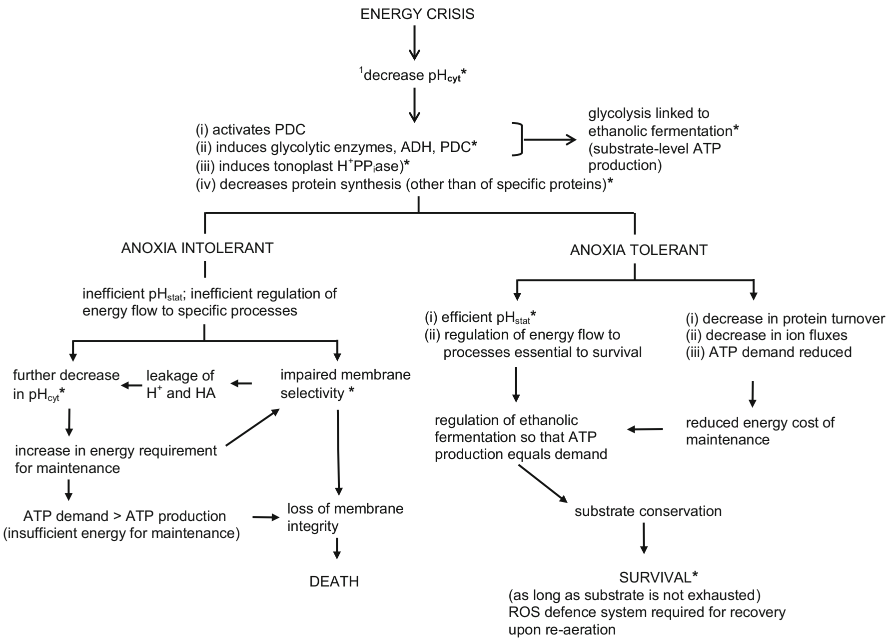

Fig. 3 A scheme for events that follow the onset of anoxia, and therefore an energy crisis, in plant tissues, indicating possible mechanisms of tolerance and causes of intolerance to anoxia (Reproduced, with a few modifications, from Greenway and Gibbs (2003), Functional Plant Biology, with permission of CSIRO Publishing). *Asterisks* are as used by Greenway and Gibbs (2003) to indicate processes for which substantial evidence exists, whereas other processes indicated are supported by limited evidence or in some cases are speculative. Note: [1]Decreased pH of the cytoplasm was regarded as a primary signal in anoxia (Greenway and Gibbs 2003). Responses of plants to conditions of hypoxia (i.e., low, but not zero, O_2) could involve sensing of changes in: (i) energy charge, (ii) cytosolic pH, (iii) cytosolic Ca^{2+} activity, (iv) levels of ROS and RNS (reactive oxygen and nitrogen species, respectively), (v) possibly O_2, and in the longer term, (vi) altered carbohydrates availability (see text). *ADH* alcohol dehydrogenase, *ATP* adenosine triphosphate, *H^+PP_iase* transmembrane proton carrier (proton pyrophosphatase), *PDC* pyruvate decarboxylase, *pH_{cyt}* cytoplasmic pH, *ROS* reactive oxygen species

quickly dismutate to hydrogen peroxide (Blokhina et al. 2003). The antioxidant defense system consists of redox-active small molecules and enzymes involved in either the direct detoxification of ROS or in regeneration of antioxidant molecules to their reduced states that can "mop up" ROS (Blokhina et al. 2003; Vartapetian et al. 2008; Colmer and Voesenek 2009).

Phytotoxins

ROL is the first line of defense against soil-generated phytotoxins. Chemically reduced elements such as Fe^{2+}, Mn^{2+}, and H_2S are converted to their oxidized counterparts in, and at the outer fringes of, an oxygenated rhizosphere

(Armstrong 1979; Armstrong et al. 1992; Colmer and Voesenek 2009). The overlapping oxygenated rhizospheres of closely spaced laterals may be particularly effective at protecting from phytotoxins by preventing initial production of reducing compounds and anaerobic digestion of organic matter, as well as encouraging an aerobic microflora and nitrogen transformations to nitrate (Colmer and Voesenek 2009). Subapical barrier formation in the exodermis is a second line of defense (Armstrong et al. 2000; Watanabe et al. 2013) and probably most necessary for the maturing parts of adventitious roots prior to lateral root emergence.

Future Challenges

Plant metabolism enabling survival of severe hypoxia/anoxia is a research area attracting much attention. In particular, sensing and signal transduction pathways are important to elucidate to understand wetland plant physiology, and these are also potential targets for use in crop improvement of flooding tolerance. Responses to submergence, of which altered O_2 supply is one important factor, involves perception of several environmental and plant changes and various transduction pathways (Voesenek et al. 2006). Responses to low O_2 in plant tissues could involve sensing of changes in: (i) energy charge, (ii) cytosolic pH, (iii) cytosolic Ca^{2+} activity, (iv) levels of reactive oxygen and nitrogen species (eg., NO), (v) possibly O_2, and (vi) altered carbohydrate availability (Greenway and Gibbs 2003; Licausi and Perata 2009). Recently, responses of expression of some genes to low O_2 availability have been shown to involve degradation of specific transcription factor regulatory proteins (Gibbs et al. 2011; Licausi et al. 2011). The various possible sensing and signaling processes in O_2-deficient cells and tissue need to be evaluated further to develop an integrated understanding (e.g., models) of the various regulatory pathways, for a range of sensitive (i.e., dryland) and tolerant (i.e., wetland) species.

Abstract

Plants form associations with fungi in leaves, stems, and roots. Mycorrhizas develop in roots. Generally, plants benefit through increased nutrition in exchange for carbohydrates. Mycorrhizas are associated with increased tolerance to environmental stressors and competitive ability. While water quality and quantity affect mycorrhizas, several types are found in wetlands. Arbuscular mycorrhizas are the most widespread, being characterized by internal branched structures (arbuscules). Dark septate endophytes are a poorly studied but wide-ranging group that are seen as darkly colored hyphae on and within roots. Ectomycorrhizas are associated with tree species and while present in wetlands, their function is unclear. Orchids and ericaceous plants form mycorrhizas called orchid and ericoid mycorrhizas; their functions in wetland plants are also poorly studied. Fungi living in shoot tissues (shoot

Introduction

Many plant species form intimate associations with fungi. The associations may physically take place in leaves, stems, and roots. Mutualistic associations occurring in roots are termed mycorrhizas (myco = fungus, rhiza = root). These associations are formed by the majority of plant species and involve a wide range of fungal groups (Smith and Read 1997). In above ground tissues, stems, and leaves, the fungal partners usually reside within the host tissues and are referred to as shoot endophytes (endo = inside, phyte = plant). The role of mycorrhizal fungi and shoot endophytes in wetlands is poorly understood. However, with increased recognition of wetland importance and greater attention being paid to wetland processes, their prevalence and their *potential* contributions to wetland plant growth and community structure are receiving greater attention.

Mycorrhizal Associations

Arbuscular Mycorrhizas Of the various types of mycorrhizal associations, arbuscular mycorrhizas (AMs) are the oldest and most widespread (Smith and Read 1997). Evidence of arbuscular mycorrhizal associations has been found in fossils of the earliest vascular plants (Taylor et al. 1995). The majority of vascular plant families and over 85% of vascular plant species form arbuscular mycorrhizal associations with soil-dwelling fungi belonging to the phylum Glomeromycota (Schüßler et al. 2001). Outside of a host root, the fungus persists either as spores or as a network of thin, thread-like structures called hyphae, which grow throughout the soil (Fig. 1). In the presence of a suitable host, the fungal hyphae grow toward the host root following a trail mapped out by signaling compounds released by the host. Once a hypha contacts the epidermal surface of the host plant root, a specialized structure, the appressorium, is formed that facilitates the entry of the fungus into the host root (Garriock et al. 1989). The fungus, upon breaching the epidermis, enters the cortex of the root and proliferates. Within the root the fungal partner forms highly branched structures, arbuscules, or in some cases hyphal coils, within cortical cells (Peterson et al. 2004). It is largely through these structures that the exchange of materials occurs between the fungus and the plant. The plant provides the fungus, an obligate symbiont, with carbohydrates, while the fungus provides the plant with minerals and water. The enhanced mineral nutrition in mycorrhizal plants confers a greater capacity to withstand environmental stressors such as drought, contaminant

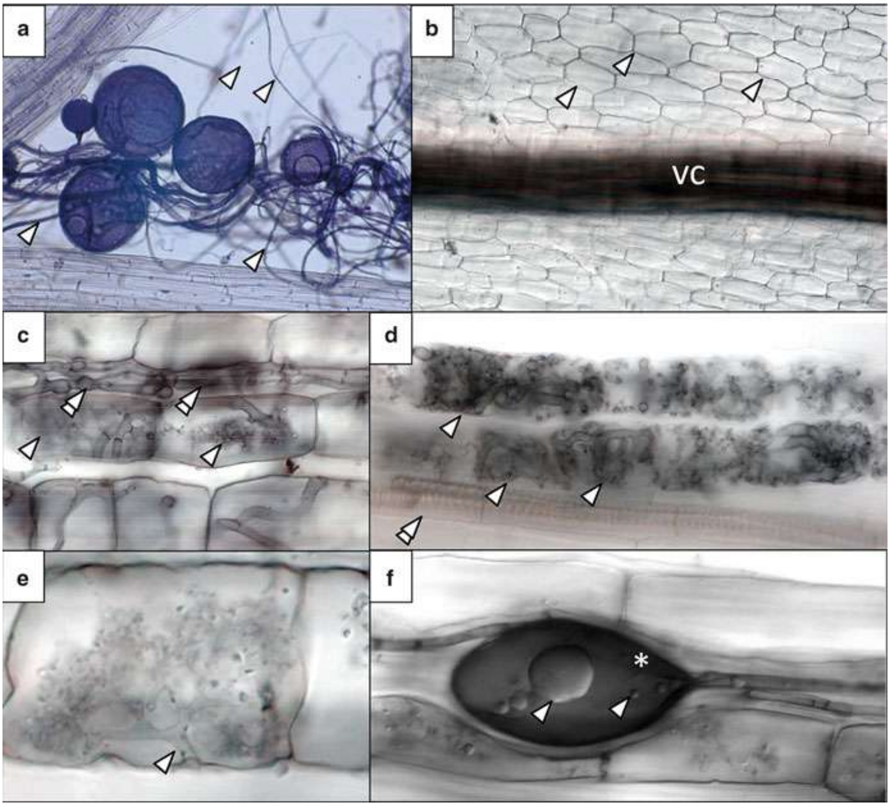

Fig. 1 Arbuscular mycorrhizal fungi. Arbuscular mycorrhizal fungi are the oldest and most widespread mycorrhizal symbiosis. Outside of the host root, the fungal partner produces thread-like extraradical hyphae (**a**; *arrowheads*) that forage for nutrients and contribute to soil stability. Larger, globular spores are produced that serve as fungal propagules allowing the fungus to survive inhospitable environmental conditions and provide a mechanism for dispersion to new areas. Clearing of plant roots by high temperature and caustic solutions break down the cellular contents, leaving only plant cell walls and fungal hyphae (**b**). In a noncolonized root, the lignified vascular cylinder (**b**; *VC*) is visible. Only the cell walls (**b; arrowheads**) remain of cortical cells (**b; asterisk**). Following staining with a stain specific for mycorrhizal fungal cell walls (e.g., Chlorazol Black **e**), arbuscular mycorrhizal fungi show up as gray structures within the cortical cells of the host (**c–f**). Internal to the host plant cell wall, the fungal partner produces arbuscules (**c**, **d**, **e**; *arrowheads*), highly branched structures involved in the exchange of materials between the fungus and its host, and intracellular hyphae (**c**; *double arrowheads*). Spiral secondary cell wall thickenings (*double arrowheads*) of the host vascular tissue are evident in **d**. After entry through the cell wall, the trunk hyphae (**e**; *arrowhead*) branches dichotomously. Subsequent dichotomous branches give rise to the highly branched arbuscules. Storages structures, vesicles, (**f**; *asterisk*) are also produced within the host root. Lipid droplets (**f**; *arrowheads*), an energy reserve are evident within the vesicle. Note the noncolonized cortical cells above and faint arbuscules (*arrowhead*) below the vesicle (Images are reprinted from Aquatic Botany, 92/2, Kevin J. Stevens, Misty R. Wellner, Miguel F. Acevedo, Dark septate endophyte and arbuscular mycorrhizal status of vegetation colonizing a bottomland hardwood forest after a 100 year flood, Pages 105–111. Copyright 2010 with permission from Elsevier)

toxicity, extremes in temperature, and resistance to microbial disease. The improved nutritional status of colonized plants also results in greater competitive ability (Fig. 1).

Early researchers predicted that AM would not be present in wetland plants because AM fungi are aerobic organisms requiring oxygen for respiration. Since wetlands are often anaerobic, it was believed that AM fungi could not survive in these habitats. The absence of AMs in wetlands was supported by an often reported trend towards reduced AM colonization levels in plants sampled along a water gradient from low to high water availability. However, as more researchers turned their attention to wetlands and wetland plants, it was recognized that AM are prevalent in wetlands. Arbuscular mycorrhizal fungi colonize plants in diverse wetland habitats including prairie potholes (Wetzel and van der Valk 1996), marshes and fens (Bohrer et al. 2004), cypress swamps (Kandelepas et al. 2010), northern peat bogs (Thormann et al. 1999), and bottomland hardwood forests (Stevens et al. 2009).

AM associations are highly responsive to environmental conditions. AM colonization levels are affected not only by the amount of water availability (Stevens and Peterson 1996) but also by the timing, frequency, and duration of flooding/drought. Furthermore, AM colonization levels are influenced by water quality. As in terrestrial habitats, AM colonization tends to decrease with increasing soil phosphorus availability (Stevens et al. 2002; White and Charvat 1999). As oxygen is depleted in flooded soils, soil redox potential decreases. This change in water chemistry impacts the availability of soil nutrients. The bioavailability of the macronutrient phosphorus increases with decreasing soil redox potential. In some cases, it may be this increased phosphorus availability, rather than water availability, that leads to reduced levels of colonization in flooded soils (Stevens et al. 2002). Increasing soil/water salinity (Carvalho et al. 2003), concentrations of heavy metals (Leyval et al. 1997), and urban contaminants including the widespread antimicrobial triclosan (Twanabasu et al. 2013a, b) can also lead to reductions in colonization levels. Given that increased urbanization and climate change have been, or are, predicted to influence water quantity, availability, and quality, impacts on mycorrhizal communities are likely.

The importance of AM fungi in wetland ecosystems is unclear. Given their ability to acquire and transport nutrients to their host plants, they play a role in nutrient cycling. Fungal hyphae are orders of magnitude smaller in diameter than host root systems and have the capacity to bind soil particles. Soil binding is further facilitated by the production of glomalin, a glycoprotein that essentially "glues" soil particles together (Wright and Upadhyaya 1998; Rillig 2004); hence, AM fungi play a role in soil stability. The contribution of AM to plant performance varies. AM-inoculated plants often show differences in patterns of resource allocation between shoots and roots and differences in shoot and root morphology compared to noncolonized plants. This response is species-specific and the magnitude of the response differs even among closely related wetland species. Although mycorrhizal interactions are largely assumed to be mutually beneficial, the advantages to the plant host can vary under different environmental conditions and the nature of the relationship may range from mutualistic to parasitic under different conditions

(Johnson and Graham 2013). The species specific nature of AM associations and differential effects of environmental characteristics on colonization levels suggests that changes in AM community dynamics may lead to changes in wetland plant community structure.

Dark Septate Endophytes (DSE) Dark septate endophytes (DSE), also known as dark septate fungi (DSF), are recorded in the fossils of the aquatic angiosperm, *Eorhiza arnoldii*, indicating an association with wetland plants that extends back to the Eocene period (Klymiuk et al. 2013). DSEs are darkly pigmented ascomycetous fungi that colonize host roots by proliferation of their septate hyphae either through intercellular spaces or from cell-to-cell in host root tissues (Peterson et al. 2008) (Fig. 2). Fungal hyphae, extending from DSE propagules in the soil, contact the host root and form a network of mycelia over the root surface. Hyphae on the surface enter the host tissue via epidermal cells, root cap cells, or wounds caused by emergence of lateral roots (Peterson et al. 2004). Intraradical hyphae (hyphae within the root) proliferate and enter host epidermal and cortical cells. The hyphae may become melanized and form clusters of inflated, round, thick-walled cells called microsclerotia within cortical cells (Jumpponen and Trappe 1998). These microsclerotia contain polysaccharides, proteins, and polyphosphates (Yu et al. 2001), which are believed to enable them to remain in the older roots and act as an inoculum source for the colonization of new roots (Peterson et al. 2004, 2008).

DSE are thought to access carbon, nitrogen, and phosphorus in litter and soil, which are bound to organic compounds and not immediately available to plants. Therefore, like other mycorrhizas, DSE may enhance the performance of their hosts by improving host plant mineral nutrition. While there is limited experimental data

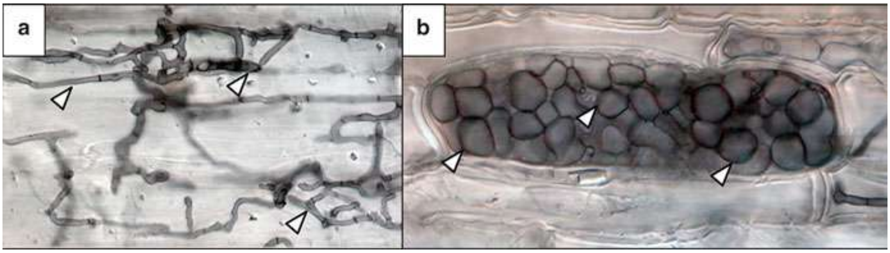

Fig. 2 Dark Septate Endophytes. Dark septate endophytes are visualized in the same manner as arbuscular mycorrhizal fungi (clearing and staining of the roots) and can often be found cooccurring with them. Hyphae within the host root, intraradical hyphae (*A; arrowheads*) enter the epidermal and cortical cells of the root. Exchange of materials between the host plant and fungus occurs through the intraradical hyphae. Within some cells, the hyphae may become melanized and produce microsclerotia, clusters of round thick-walled cells (*B; arrowheads*). Microsclerotia contain storage compounds (polysaccharides, proteins, and polyphosphates) and are thought to act as an inoculum source, facilitating the colonization of new roots (Images are reprinted from Aquatic Botany, 92/2, Kevin J. Stevens, Misty R. Wellner, Miguel F. Acevedo, Dark septate endophyte and arbuscular mycorrhizal status of vegetation colonizing a bottomland hardwood forest after a 100 year flood, Pages 105–111. Copyright 2010 with permission from Elsevier)

supporting this view, studies have shown DSE inoculation to improve plant performance compared to noninoculated plants when assessed in terms of root, shoot, and total biomass (Haselwandter and Read 1982; Newsham 1999). By improving access to carbon, nitrogen, and phosphorus, compounds essential to growing plants, DSE may be particularly beneficial during seedling establishment (Peterson et al. 2004; Solaiman and Hirata 1997; Stevens et al. 2011).

DSE are ubiquitous in terrestrial ecosystems from tropical forests (Rains et al. 2003) to alpine vegetation (Read and Haselwandter 1981). In North America, DSE have been found in wetland habitats from northern boreal wetlands in Canada to coastal wetlands of Louisiana (Wilson et al. 2004; Kandalepas et al. 2010) and from wetland types including peat lands, bogs, fens, lakes, streams, bottomland hardwood forests, and degraded marshes (Weishampel and Bedford 2006; Kandalepas et al. 2010; Kai and Zhao 2006; Kohout et al. 2012). Kandalepas et al. (2010) found DSE colonization was more prevalent than AM colonization in a degraded marsh in coastal Louisiana. They found all 18 species of the marsh plants colonized by DSE. Similarly 31 of 37 wetland species in a bottomland hardwood forest were colonized by DSE (Stevens et al. 2009), while only one species in 24 hydrophytes from lakes and 3 species among 17 stream hydrophytes were colonized by DSE (Kai and Zhao 2006). DSEs are found more commonly in monocots compared to dicots (Kandalepas et al. 2010; Weishample and Bedford 2006); however, additional studies are required to identify if this trend is seen on a larger scale and in a greater number of wetland habitats.

Orchid Mycorrhizas The family Orchidaceae is the largest angiosperm family. Plants in this family may grow in soil, as epiphytes, on other plants, or on rock surfaces. Many orchid species grow in wet habitats. Orchids produce very minute seeds devoid of endosperm (Fig. 3). Consequently, they possess insufficient nutrient reserves for seed germination and seedling growth and depend upon a fungal host for nutrient acquisition during germination and early seedling development (Peterson et al. 1998). Mycorrhizas have been extensively studied in terrestrial orchids; however, wetland orchids have generally been overlooked. Some recent studies have found that wetland orchids do harbor mycorrhizal fungi. The presence of mycorrhizal fungi has been noted by several authors in the bog orchid genus *Habenaria* (Cowden and Shefferson 2013; Stewart and Zettler 2002). In addition, eight orchid species from wet treeless habitats in Hungary and an *Epipactis thunbergii* in man-made wetlands in Hiroshima, Japan (Cowden and Shefferson 2013; Illyes et al. 2009) were found colonized by symbiotic fungi. In areas where the establishment of wetland orchids is an integral component of wetland creation or remediation efforts, Stewart and Zettler (2010) suggest *in vitro* germination and inoculation of cultured wetland orchids with mycorrhizal fungi to improve transplant success. The effects of environmental conditions on orchid mycorrhiza are poorly understood; however, evidence suggests that the saturated soils and flooded conditions are not an impediment to orchid mycorrhizal colonization. Illyes et al (2009) found orchid species colonized by symbiotic fungi from the fungal genera *Epulorhiza*, *Sebacinaceae,* and *Ceratobasidiaceae* in wetland habitats with water regimes ranging from standing water to well-drained areas.

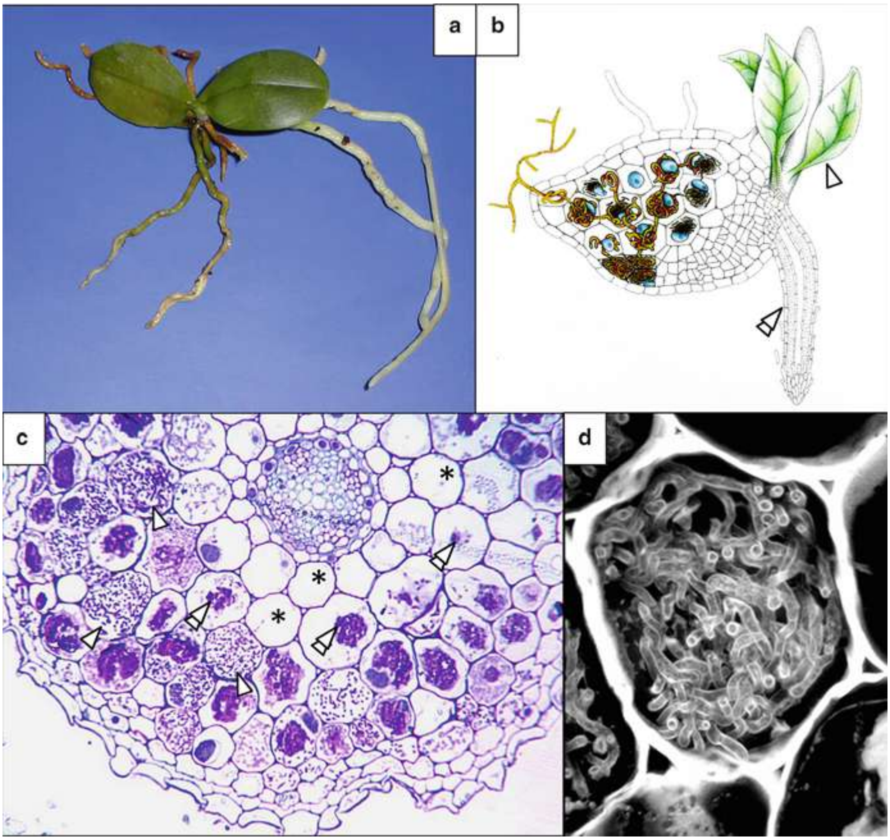

Fig. 3 Orchid mycorrhiza. While stems, leaves, and roots are clearly visible on a mature orchid plant (*A*), orchids are unique in that these structures are absent in the seed. Orchids produce numerous tiny seeds, lacking the storage tissue endosperm and containing an undifferentiated embryo lacking shoots and roots. Colonization of the seed by a fungal partner is necessary for the provision of carbohydrates needed for the seedling to develop. Following colonization, the embryo develops into a protocorm that further develops into a seedling. The shoot (*arrowhead*) and root system (*double arrowhead*) are produced by the protocorm (*B*). Within parenchyma cells of the protocorm, the fungal hyphae coils forming structures called peletons. Extensive colonization occurs in the roots (*C*). Cortical cells containing purple stained peletons contrast sharply with noncolonized cortical cells (*asterisks*). Peletons are short-lived and roots contain both viable (*C; arrowheads*) and degraded (*C; double arrowheads*) peletons. The highly coiled nature of the peleton is evident in an image obtained from a laser scanning confocal microscope (LSCM) image (*D*). By obtaining several optical slices through a specimen, the LSCM is able to construct three-dimensional images that reveal features not readily apparent with conventional light microscopy (Images are reprinted from Mycorrhizas: Anatomy and Cell Biology Images CD. R. Larry Peterson, Hugues B. Massicote, Lewis H. Melville, Forest Phillips. Copyright 2006 with permission from NRC Press)

Ericoid Mycorrhiza A unique mycorrhizal association is formed by some members of the diverse plant order Ericales and some ascomycetous fungi. Species in the Ericales include the economically valuable *Vaccinium* spp. (cranberry and blueberries) and several wetland species including *Andromeda polifolia* (bog rosemary), *Rhododendron canadense* (rhodora), *and Ledum groenlandicum* (Labrador tea). The roots involved in forming ericoid mycorrhizas are referred to as “hair roots” due to their very small (<100 um) diameter (Fig. 4). Anatomically, the hair roots consist of an epidermis, a very much-reduced cortex consisting of two layers, an outer hypodermis and inner endodermis, and a central core of vascular tissue comprised of small tracheary elements and sieve elements (Peterson et al. 2004). Colonization begins when fungal hyphae reach the root epidermal surface. Here, the fungal hyphae may branch and form a mantle-like structure or form “runner hyphae” that branch and facilitate the colonization of epidermal cells. Colonization of the host is restricted to enlarged root epidermal cells. Entry into an epidermal cell may be preceded by the formation of an appressorium although this does not occur in all cases. Once the epidermal cell wall has been penetrated, each hypha forms a coiled or branched structure, the hyphal complex, within the boundaries of the host cell wall. As with arbuscular mycorrhizal fungi, the hypha does not penetrate the plasma membrane (Perotto et al. 1995). The exchange of materials between the plant and fungus occurs through the hyphal complexes.

The role of ericoid mycorrhiza in wetland plant species has received little attention; however, information on the role of ericoid mycorrhizae in heath vegetation provides an indication of potential wetland importance. The fact that ericaceous plants are found in nutrient poor soils suggests that ericoid mycorhiza play a role in host nutrient status. The extent to which the extraradical mycelia of ericoid mycorrhizae extends beyond the host root system is hampered by the nature of peaty soils in which they often grow; however, measurements of <1 cm have been reported in sandy soils (Read 1984). Ericoid mycorrhiza can either produce the necessary enzymes or mobilize organic and inorganic forms of phosphorus (Smith and Read 2008). In heathlands, ericoid mycorrhiza facilitate nitrogen uptake absorbing nitrogenous compounds such as nitrate, ammonium, and amino acids and translocating them to the host. In addition, ericoid mycorrhiza are able to produce enzymes needed to access nitrogen bound up in more complex organic compounds such as pectin, cellulose, hemicellulose, and lignin found in plant cell walls and chitin found in fungal cell walls and invertebrate exoskeletons (Read 1996). Ericoid mycorrhizae also provide a measure of protection against the heavy metals aluminum, arsenic, cadmium, copper, and zinc (Bradley et al. 1982; Denny and Ridge 1995). It remains to be seen if these attributes are also expressed in wetland habitats.

Ectomycorrhizas While arbuscular mycorrhizal fungi are associated primarily with herbaceous vegetation, ectomycorrhizas are often associated with tree species and, although less frequently, shrubs and herbaceous plants (Fig. 5). Ectomycorrhizal associations involve an estimated 5000–6000 basidiomycetous and ascomycetous fungi (Smith and Read 2008). These fungi include many economically important mushroom-producing and truffle-producing taxa. Similar to arbuscular mycorrhiza, ectomycorrhizal fungi produce an extensive network of hyphae extending out from the host root system that is involved with the acquisition of water, nutrients, and

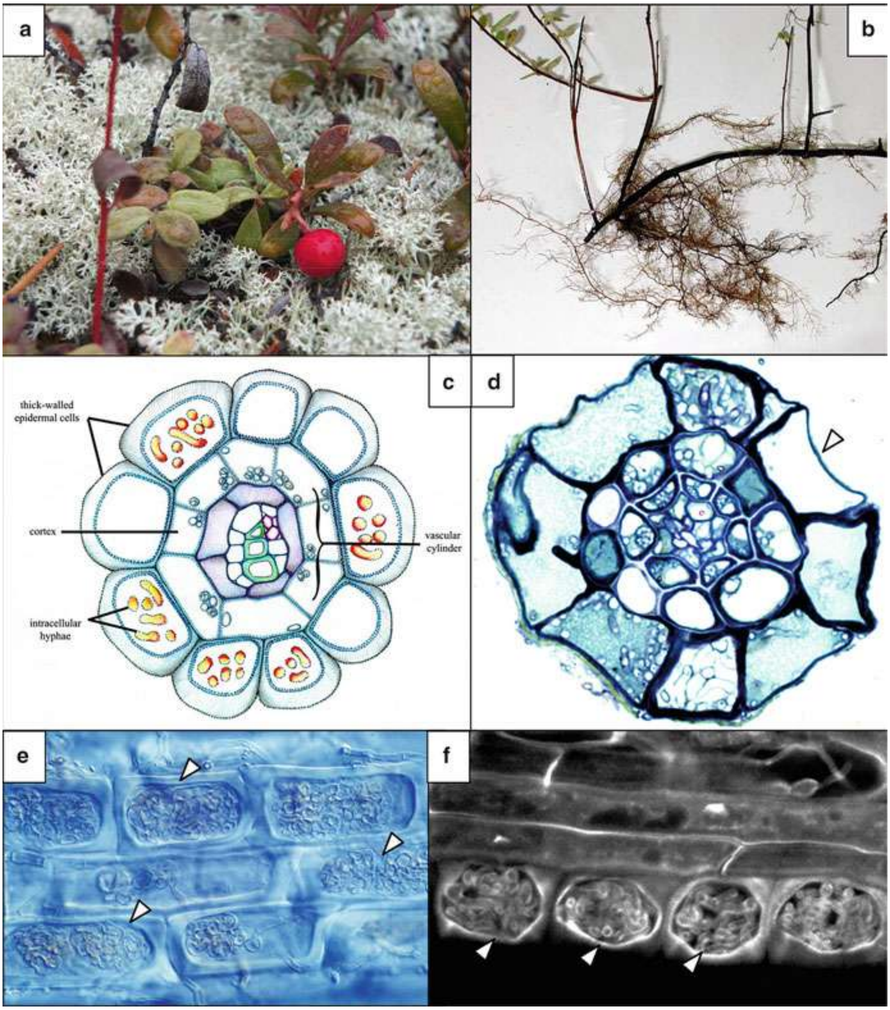

Fig. 4 **Ericoid Mycorrhiza**. Members of the order Ericales, including bog/fen species such as cranberry (*Vaccinium* sp; *A*) and Labrador tea (*Ledum groelandicum*; *B*) form ericoid mycorrhiza with ascomycetous fungi. The fine roots of ericaceous plants that are colonized are considerably reduced and often less than 100 um in diameter. The cortex consists of only two cell layers while the vascular cylinder consists of few xylem tracheary elements and phloem sieve elements (*B* and *C*). Colonization is restricted to the epidermal cells. Note the extensive colonization of epidermal cells compared to a noncolonized epidermal cell (*D; arrowhead*). The extensive hyphal coiling that occurs within the epidermal cells is evident in longitudinal sections (*E and F; arrowheads*). Note that the image in *E* was obtained with transmitted light microscopy while the image in *F* was obtained with laser scanning confocal microscopy (Images B–F are reprinted from Mycorrhizas: Anatomy and Cell Biology Images CD. R. Larry Peterson, Hugues B. Massicote, Lewis H. Melville, Forest Phillips. Copyright 2006 with permission from NRC Press)

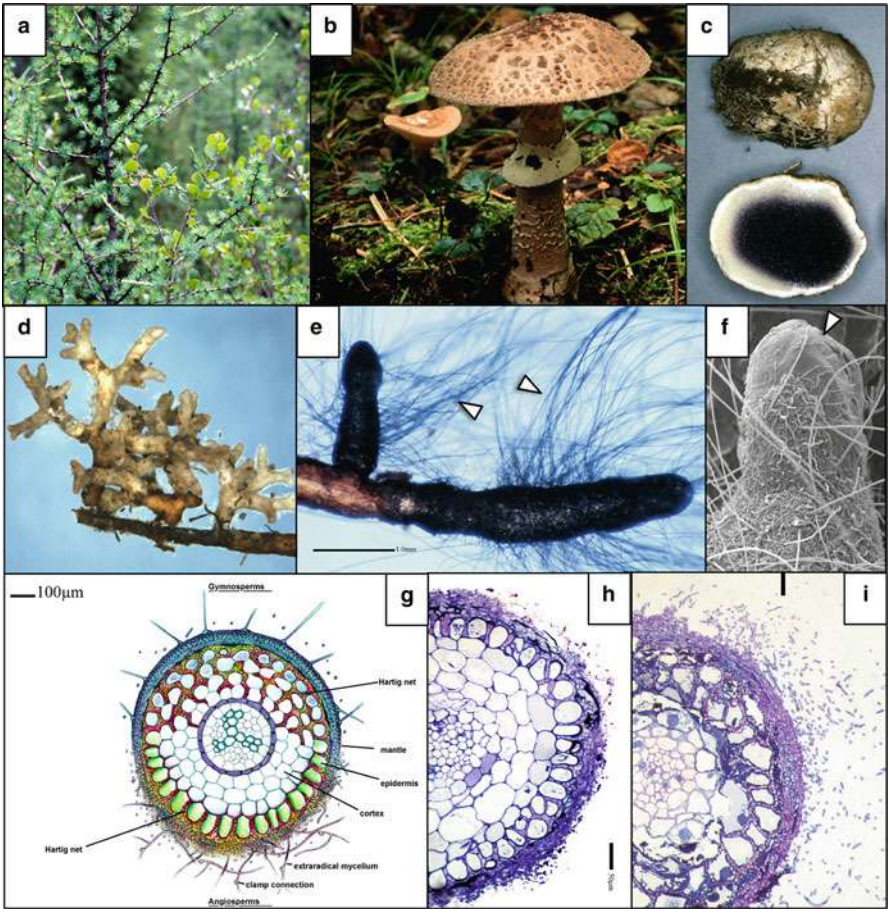

Fig. 5 **Ectomyorrhiza**. Ectomycorrhizal associations form between tree species such as tamarack (*A*; *Larix laricina*) and members of fungal taxa Basidiomycota and Ascomycota. The fungal taxa include mushroom forming species (*B*) and fungi that produce belowground fruiting bodies (*C*). Note that in *C*, the subterranean fruiting body has been cut in half to reveal the inner dark sporogenous tissue. Colonized roots often differ morphogically from noncolonized roots and typically display a dichotomous (y-shaped) branching pattern resulting in clusters of roots (*D*). Hyphae will envelop the roots forming a “mantle.” The color, thickness, density, and morphology of hyphae in the mantle differ among fungal taxa. For example, compare the light mantle hyphae in *D* to the dark mantle hyphae in *E*. Also note the extensive extraradical hyphae (*arrowheads*) emanating from the mantle in *E*. An image obtained from a scanning electron microscope further illustrates the extent of the mantle. Compare the sparsely colonized root tip (*arrowhead*) to the more densely covered region directly below the tip (*arrowheads*). Internal to the mantle, a network of fungal hyphae, the Hartig net, develops between cells of the host root (*G*–*I*). In angiosperms, this layer forms only between epidermal cells (*G* and *H*) whereas in gymnosperms the Hartig net extends throughout the cortex (*G* and *I*) (Images are reprinted from Mycorrhizas: Anatomy and Cell Biology Images CD. R. Larry Peterson, Hugues B. Massicote, Lewis H. Melville, Forest Phillips. Copyright 2006 with permission from NRC Press)

their subsequent transportation to the host plant. Extraradical hyphae, hyphae extending out from the host root, may occur singly or in groups of interwoven and interconnected hyphae called rhizomorphs. Modifications of hyphae within the rhizomorphs permit them to function in the rapid, high volume transport of materials from individual peripheral hyphae to the host. Two structures distinguish ectomycorrhizal fungi from other mycorrhiza, the presence of a mantle and Hartig net. During initial stages of colonization process, when an extraradical hypha contacts the epidermal surface of a compatible host root, the hyphae begin to branch and spread over the root surface (Peterson and Farquhar 1994). The resulting hyphal layer surrounding the root is called the mantle. The extent of epidermal root surface covered by the mantle varies but frequently the entire root surface is covered by hyphae that are several layers thick. The layers of the mantle may have unique morphological characteristics and be further classified as inner, middle, and outer mantle. A Hartig net develops from hyphae of the inner mantle. This net is a specialized structure that is involved in the exchange of materials between the plant and its fungal partner. In angiosperm species, the Hartig net develops around only epidermal cells and does not enter the cortex. In conifer species, however, the Hartig net includes several layers of cortical cells in addition to the epidermis (see Peterson et al. 2004 for details of ectomycorrhiza structure).

Many tree genera that are frequently found in wetlands (e.g. *Alnus*, *Salix*, *Pinus*, *Picea*) form ectomycorrhizal associations. However, we are unaware of any studies that have ascertained the role of ectomycorrhizae in wetland plants. Studies that have compared responses of colonized and noncolonized plants to environmental stressors under wetland conditions are lacking. Initial observations suggested that ectomycorrhizal colonization was reduced in wet soils (Slankis 1974), possibly due to anaerobic conditions, and resulting changes in the availability of soil-derived nutrients and toxins. This reduction in colonization with increasing water availability led to an investigation of ectomycorrhizal colonization as an indicator of hydrologic conditions for wetland delineations (Vasilas et al. 2004). This trend towards a reduction in colonization with increasing water availability may not necessarily pertain to all ectomycorrhizal species equally. Robertson et al. (2006) in an investigation of ectomycorrhizal communities of black spruce (*Picea mariana*) occurring in upland and wetland habitats in central British Columbia, Canada, found that while ectomycorrhizal species richness was greater in upland compared to wetland areas, each habitat type studied (upland and wetland) supported approximately 20 morphologically distinct mycorrhizal types. Furthermore, while some ectomycorrhizal fungal groups were more frequently found in upland compared to wetland habitats, this was not the case for all fungi and some were found with equal frequency in both wetland and upland areas.

Shoot Endophytes

Foliar endophytes, fungi that live within leaf tissue without causing any symptoms of disease to their hosts, may be a key component to maintain healthy wetland plant communities. Foliar endophytes are ubiquitous, and they have been found in all plants that have been examined to date. These cryptic fungi, long overlooked in the literature, are thought to be beneficial to their plant hosts, as they not only live within plant tissue without causing any signs of disease but also have been found to increase their hosts' fitness and competitiveness. Primarily, these fungi have a mitigating effect on plant responses to extreme environmental demands, such as extreme temperatures, high salinity, flooding, drought, and herbivore pressure (Bacon 1993; Malinowski et al. 1997; Arechavaleta et al. 1992; Clay et al. 1993; Marks and Clay 1996; Clay 1988; Belesky and Malinowski 2000; Van Bael et al. 2012; Colbentz and Van Bael 2013).

Shoot endophytes are a diverse group and their patterns of diversity and community composition have been attributed to many biotic and abiotic factors. In general, endophytes that are horizontally transmitted become more diverse with increasing leaf age (Arnold and Herre 2003), allowing time for more endophytes from surrounding plants to colonize younger plants. Endophyte diversity also increases with decreasing latitude (Arnold and Lutzoni 2007), a trend that has been observed for other taxa (Pianka 1966). Indeed, endophytes in the tropics have been shown to be "hyperdiverse" (Arnold et al. 2000), contributing substantially to fungal biodiversity. Arnold et al. (2000) were able to isolate dozens of isolates from single leaves. Endophyte colonization by any particular endophyte species, however, depends on host identity and physiology, as well as the interaction between host identity and the environment (Redman et al. 2001; Ahlholm et al. 2002; Gange et al. 2007; Hashizume et al. 2008; Hoffman and Arnold 2008). Host identity and the interaction to its environment may influence leaf chemistry, which affects colonization by any particular endophyte (Arnold and Herre 2003). Other factors that affect colonization by endophytes include plant physiology (Redman et al. 2001) and external leaf characteristics such as trichome density (Valkama et al. 2005). Environmental factors that have been implicated in influencing endophyte biodiversity and community composition are precipitation (Elamo et al. 1999), acid rain (Helander et al. 1993), soil moisture (Blodgett et al. 2007), soil nutrient content (Eschen et al. 2010), temperature (Hashizume et al. 2010), and altitude (Hashizume et al. 2008). In addition, stand density (Saikkonen et al. 1998) and plant diversity also affect endophyte diversity (Arnold et al. 2000).

The advantages that plants experience in the presence of endophytes may depend on the composition of endophyte communities colonizing the plant. Also, the composition of endophytes within plants after a disturbance may differ from that prior to the disturbance. Damage to leaves alters endophytic composition from a few host-specific endophytes to many cosmopolitan endophytes (Fail and Langenheim 1990), and endophyte species richness decreased in stressful conditions (Blodgett et al. 2007; Kandalepas 2012). The new endophytic communities within damaged plants may generate new dynamics within a plant host, which could either increase plant resistance to subsequent damage or decrease plant resistance to subsequent stress, herbivory, and disease. Also, new endophytic dynamics could alter an individual's competitive ability or fitness.

The ecology of shoot endophytic fungi is poorly studied. What is known is mostly from upland and agricultural studies (but see Redman et al. 2011; Kandalepas 2012). Few studies have sought to quantify shoot endophytes in wetland species but those that have (Kumaresan and Suryanarayanan 2001; Kandalepas 2012) have demonstrated that foliar endophytes are prevalent in wetlands. Many of the environmental characteristics that affect shoot endophyte ecology are altered either by anthropogenic activities or by hydrological changes associated with climate change. For example, canal construction in southeastern Louisiana wetlands has resulted in rapid erosion and, together with logging ditches, saltwater intrusion has occurred further inland. Levees and spoil banks from oil and gas canals have created impoundments, in which water first becomes anoxic and then toxic. Changes in water quality (salinity, nutrient levels) and quantity are well documented following hurricanes as is the significant physical damage or loss of vegetation. It is important to determine which endophytes exist in natural wetland systems and whether their community structure changes with the continued anthropogenic activity and climate change (Day et al. 2007). By understanding such dynamics, managers may be able to use fungi to promote the health of coastal plants under this additional pressure.

Conclusions

Many wetland plant species form intimate associations with shoot and/or root fungal endophytes. In some cases, these associations have existed for millennia. While the role and importance of endophytes in wetlands is largely unknown, there is evidence to suggest that endophytes play important roles in nutrient acquisition, herbivore defense, tolerance of soil and water contaminants, tolerance of altered hydrology (flooding and drought), and plant/plant competitive interactions. Other roles are likely to be found. Environmental changes associated with increased anthropogenic disturbance and climate change, such as altered water quality and changing hydrological patterns, may affect several aspects of endophyte ecology. Additional research is needed to fully understand the contributions that endophytes make to wetland plant ecology and ultimately how they impact valued wetland ecosystem services. Whereas the limited information possessed to date is often based on studies manipulating one environmental factor, future studies must include an assessment of the interplay among several environmental factors and endophyte ecology.

Introduction

Wetlands are dynamic areas, open to influence from natural and human factors. In order to maintain the way that wetlands function, their biological diversity, and the benefits that they provide to human society, it is essential to understand their management requirements. However, management can take many forms. Human history is littered with examples of unsustainable wetland management. For instance, the Fens of Eastern England once covered an area of approximately 500 km^2. During the seventeenth century the preeminent Dutch drainage engineer Cornelius Vermuyden undertook the task of draining the Great Fen in Cambridgeshire. Two new channels, the Old Bedford River and the Forty Foot Drain, and the drainage channel known as the New Bedford River were constructed. The managed drainage of the Fens facilitated the intensification of agriculture. However, the drying of the land caused the carbon-rich peat soil to mineralize and shrink rapidly due to oxidation, lowering much of the land to a level below that of the newly excavated drainage channels. By the end of the seventeenth century much of the land reclaimed by Vermuyden was again waterlogged and would remain so until the arrival of steam-powered pumps in the nineteenth century. Pumped drainage continued well into the twentieth century. However, in the latter part of the twentieth century attempts have been made to reconcile the potentially conflicting needs of intensive agriculture and the wider ecosystem services provided by the residual wetland areas. More sustainable wetland management techniques are slowly being introduced to reverse wetland loss and degradation and to optimize benefits for human society. Therefore, the Fens of Eastern England can be seen to demonstrate the different ends of the wetland management spectrum.

Wetland Management

Wetlands play crucial roles in supporting biodiversity, the functioning of landscapes, the cycling of water and other matter, and human wellbeing. This is today most commonly summed up in terms of ecosystem services, recognizing that management of the environment and the sharing of its benefits is a matter of societal choice with economic and wider spatial and temporal implications. Sustainable management of wetlands then is an essential basis for sound ecological, resource stewardship and equitable priorities.

The diverse benefits provided by wetlands stem from the many functions that they perform. For example, wetland hydrological functions contribute to the buffering of river and groundwater flows, habitat structure and ecosystem processes purify water and air as well as sequestering carbon and aiding fishery recruitment, while chemical processes cycle nutrients. The functioning of wetlands is the basis of their capacity to produce a range of ecosystem services.

Many wetland ecosystem services have been exploited by people, both directly and indirectly. For example, wetlands directly support important fisheries and wildfowling opportunities for subsistence, trade, and recreation. Indirectly, wetland processes also purify pollutants from land use as well as domestic and industrial waste streams. The topography and fertility of wetlands also render them suitable for conversion for agricultural uses, albeit that this commonly degrades the wetland system effectively “mining” it for short-term gain and exploiting the fertility of soils that may have built up over long timescales.

Frequently, direct and indirect benefits provided by wetlands are exploited narrowly, overlooking the diversity of other supportive services that they provide and their capacity to support a diversity of human interests in both immediate and longer-term timescales. A wide range of “negative externalities” arise from this narrowly framed use of wetlands, including, for example, liberation of sequestered carbon, disruption of hydrology, increased soil erosion, and loss of habitat for wetland species. This failure to value and include into decision-making many of the benefits that wetlands provide is a major driver of the erosion of the wetland resource. Wetlands and water then are among the most profoundly and rapidly degrading habitats globally (MA 2005).

Management of Wetlands for Ecosystem Services

There are a number of uniting themes across all of aspects of wetland management. First and foremost is the importance of managing wetlands on an integrated basis, reflecting the fact that all categories of ecosystem services and the character and functioning of the wetlands that produce them are fully integrated. Also, these subsidiary reviews suggest that wetlands have to be considered within their socio-economic context, including the security of resources underpinning a diversity of livelihoods and the equity issues inherent in their management. “Wise use” provisions of the Ramsar Convention respect the need to conserve the natural character and functions of wetland systems, including the interests of all their beneficiaries.

The balance of services and of the human interests that they support differs across wetland types. Coral reefs support valuable coastal fisheries and buffer the land/water interface from storm and tidal energy; mangrove systems too provide buffering from tsunamis and other extreme events as well as providing a diversity of food and fuel wood, while upland bogs store and purify water buffering flows of fresh water that may be important to people living in downstream catchments distant from river sources. The diversity and distribution of wetland types across landscapes is important for providing the wide range of ecosystem services securing human wellbeing. However, this wider valuation of wetland diversity and distribution is not always well or adequately reflected in conventional area-based nature conservation designations.

Conflicts Over Wetland Management

It has been widely suggested that water will become as significant a source of conflict in the future as it has been in the past. This view rather overlooks the fact that the Six-Day War of 1968 between Israel and Jordan was in reality a conflict over the flows of the Jordan River, a vital resource in this arid zone of the world, and that the ensuing annexation of the Golan Heights and other territories was as much about catchment control as pure land acquisition. Saddam Hussein's internal war against insurgent Marsh Arabs in 1990s Iraq too saw the annexation of water as a weapon of war, undermining the culture of the region. The sharing of water too is a source of friction between India and Pakistan in terms of allocation of the flows of the Indus River, just one example of many conflicts over international catchments. The "Cod Wars" of the 1960s, when Iceland unilaterally imposed exclusion zones to prevent foreign trawlers overexploiting cod stocks, demonstrate the extension of resource conflicts to coastal and open seas.

However, the world commission on Dams also highlights in the final of its seven Strategic Priorities the importance of "Sharing rivers for peace, development and security." This underlines wider recognition of the view that the sharing of water is a major driver of the making and maintenance of peace, including a detailed review of "southern African hydropolitical complex" which provides heartening evidence that international agreements on water sharing were a catalyst for dialogue, enduring agreements (even throughout periods of conflict) and also a mechanism for negotiating peace between countries at war (Turton 2005).

Collaborative sharing and comanagement of wetland systems may then be crucial for the security agenda, extending wider consensus about its central role in supporting international development.

Frameworks, Drivers, and Approaches for Delivering Successful Wetland Management

There are many drivers and approaches available to deliver success for wetland management. The single most important factor in wetland management is to define clear objectives from the start of the management process. Where there are important features, such as the threatened or rare species or the maintenance of vital natural resources which maintain human wellbeing, it is essential to define distinct management objectives for each one of these features. In other words, whoever is responsible for wetland management must be clear about what it is they are trying to achieve.

The ability to deliver on the objectives of site management will always be influencing to some extent by a range of factors. It is essential that all important factors should be identified and that their impacts on the wetlands, and particularly on those important features identified in the objectives, are considered. Some of the factors which influence successful wetland management may occur within the site boundary; however, others operate at a variety of scales, for instance, at the river basin or coastal zone scale. Similarly, some of the factors may be social or political in nature, such as changes in legislation or regulatory frameworks. All of these factors need to be considered in order to deliver successful wetland management.

The identification of clear objectives and understanding of the factors which may influence their delivery should help to resolve potential conflicts. However, within any wetland site management framework it is essential that there is room for conflict resolution if such a situation arises. In order to inform both the proactive site management and the potential for reactive management of conflicts, it is essential that a clear sight monitoring program is established and maintained. It is essential to know, and be able to demonstrate to other stakeholders and interested parties, that the objectives of being achieved, or more importantly where the factor, is compromising the achievement.

Good wetland management planning should be able to identify and describe the variety of actions required to deliver on the objectives. They should be informed by the monitoring program and should be dynamic in nature. Any wetland management plan should not just identify and describe actions; they should also estimate the cost required to implement the appropriate activities to deliver upon the objectives. Continuity of affective management and monitoring is essential. Baselines may change over time as the prevailing hydrological or social conditions evolve; therefore objectives need to be continuously revisited and appropriate monitoring and management protocols maintained to deliver against the external changes.

Good wetland management planning should also clearly demonstrate how the process is being effective and efficient. This should include a valuation not just for ecological site objectives but also for social and cost-related benefits. Consideration also needs to be given to compliance with local, national, and international obligations which the site might hold. The participation and involvement of stakeholders, including local communities and indigenous peoples, should be considered essential to ensure the effective and efficient wetland management is being achieved.

Who Are Wetland Managers?

Wetland management is a process. As such, many individuals, institutions, or stakeholders may be involved in that process. Therefore wetland managers can take many forms and will vary from site to site and from country to country. The wetland managers may include individuals who are responsible for day-to-day activities, such as managing livestock, monitoring and controlling hydrological regimes, undertaking the habitat and vegetation management, or engaging with or supervising activities involving members of the public on the site. Wetland managers may also include government officials responsible for implementing local, national, or international legislation or regulation, or they may include private landowners or tenants who are responsible for long-term management of a wetland area.

In many parts of the world, wetland management is intrinsically linked with the provision of food, water, and other resources for local communities and stakeholders. For instance, Lake Chilika on the east coast of India covers some 1,165 km^2 during the monsoon season, is an internationally important wetland system which hosts a wide range of biodiversity, including over one million wintering migratory birds, and is one of only two lagoons in the world to support the Irrawaddy dolphin. Following rapid degradation from 1950 to 2000, the Lake Chilika system suffered major declines in its fisheries, the proliferation of invasive weeds, and an overall reduction in the lake area. However, significant efforts have been made since the 1990s to reverse the degradation and to enhance the management of this important wetland ecosystem. Local beneficiaries of the restoration and sustainable management of the lake include 140,000 individuals and local communities who partake in both the management of the fisheries and partly engage in tourist activities. In this situation, the local wetland managers are also the beneficiaries of their own activities.

Future Challenges

There are many challenges involved in delivering successful and sustainable wetland management. As pressures on vital wetland resources increase, the need to understand how wetlands work and the management required to maintain the benefits which flow from wetlands increases. A genuine challenge to wetland managers is to understand the range of benefits which any wetland delivers, be they expressed as numbers of threatened species, as the number of households supplied with fish, or as the insurance value of properties protected from flooding. Only when these benefits have been identified can the appropriate objectives for the site be established and consequently the necessary monitoring and management prescriptions implemented. The failure to adequately understand the management objectives of any wetland site will increase the potential for conflicts and the risk of wetlands degradation and loss.

Systems Scale Thinking for Wetland Management

48

Mark Everard

Contents

Abstract

Systems thinking explores whole systems, which behave in ways that may not be predictable from analysis of their constituent parts. Wetlands and other ecosystems comprise complex interactions of living and nonliving components and so must be treated as integrated systems of great complexity producing a range of ecosystem service outputs. Their socioeconomic context is also highly significant in understanding the benefits of wetlands and their vulnerability to human interventions, making systemic thinking essential for effective wetland management.

Introduction

Systems thinking explores whole systems, which behave in ways that may not be predictable from analysis of their constituent parts. Wetlands and other ecosystems comprise complex interactions of living and nonliving components and so must be treated as integrated systems of great complexity producing a range of ecosystem service outputs. Their socioeconomic context is also highly significant in understanding the benefits of wetlands and their vulnerability to human interventions, making systemic thinking essential for effective wetland management.

The consequences of nonsystemic management, maximizing production of one or just a few target services while overlooking others, may be a major causative factor of wetland decline. It is therefore important to consider all aspects of wetlands in management decisions, including their context within landscapes.

Narrowly framed policy and perspectives, often backed up by “ring-fenced” budgets, contribute to management of wetlands for restricted purposes, which may contribute to ongoing erosion of the quality and quantity of wetland resources. It is therefore essential to develop a more far-seeing policy base that addresses all of the ecosystem services provided by wetlands, an economic approach that values them appropriately for inclusion in decision-making processes, and an awareness of the many values of wetlands to different elements of society.

Systems Thinking and Wetlands

Systemic understandings of wetlands reveal the complexity of these ecosystems and their many, often historically overlooked, values to society. This holistic perspective provides an essential basis for informed and potentially sustainable management.

Systems Thinking

The evolution of systems thinking, particularly since the 1970s, has unlocked new understandings of how complex systems operate and provided insights into their more effective management in fields as diverse as medicine, transport, spatial planning, climate and weather prediction, and ecosystem management. A systems approach is based on understanding the properties of systems as a whole and the relationships of their components, distinct from a reductionist approach of breaking them down into constituent parts as a means to generate understanding.

Patterns and relationships within complex systems – from the interactions of amino acids in proteins to those of cellular organelles, players in a football team, or ecosystems including human-ecosystem interactions – cannot necessarily be deduced by (reductive) analysis of their constituent parts in isolation. By definition, a system has emergent properties that exceed “the sum of the parts,” such as the catalytic properties of enzyme molecules, the capacity for consciousness arising from the mass of human brain cells, or the beneficial “ecosystem services” produced by processes occurring between ecosystem constituents in wetlands or other habitats. Addressing whole dynamic systems, and the principles that govern them, aids understanding and strategic decision-making about systems as a whole.

A systems approach is central to sustainable development, which is founded on respect for the interdependent relationships not only within ecosystems, within which all elements are indissoluble, interdependent, and essential for the production of ecosystem services, but also the wider socioecological system affecting their use and continued production.

Wetlands as Systems

Wetland ecosystems, as indeed within all habitats, are in dynamic relationship with flows of energy, matter, living organisms, and human exploitation and management activities. So, while wetlands have to be addressed as systems, we have also to be aware that systems themselves are hierarchical, dependent on wider systems including the geographical and human contexts within which the wetlands occur. These flows and influences have a profound impact on ecosystem functioning and the production of ecosystem services. Diminution of the quality and quantity of wetland habitats correspondingly reduces their potential to support human wellbeing, though the net costs of significant wetland losses observed across the world have rarely been accounted for in decisions relating to the rather narrower commercial benefits of their conversion for agricultural, infrastructure, and other human purposes.

With the rise of ecosystem services as a pedagogic and management paradigm, the multiple values of the diverse services provided by wetlands and other ecosystems have come to greater prominence. Indeed, there is growing recognition, through urban management initiatives such as “Green infrastructure” and SuDS (or Sustainable Drainage Systems), that the many beneficial services provided by natural and man-made wetland systems are of themselves a form of critical infrastructure that has been for too long overlooked in decision-making (Shiva 2008).

Recognition of the multiple values of nature and their progressive inclusion within the mainstream of policy-making across government activities is being increasingly seen as a priority, for example, in the case of the UK’s cross-government June 2011 White Paper on the natural environment (HM Government 2011). These multiple values have indeed been long recognized by the Ramsar Convention through its evolving definition of “wise use” of wetlands.

Systems scale thinking for wetland management includes understanding the role of wetlands in providing a wide range of ecosystem services beneficial to society, including the resilience of the ecosystems themselves and the interdependencies between those exploiting wetland services. A well-designed or integrated system, including, for example, an ecosystem shaped over long periods of evolutionary pressures, can absorb these forces and still maintain system functionality; conversely, a poorly designed or integrated system cannot absorb external forces, causing the system to collapse (Meadows 2008). Ecosystem resilience thereby provides a bulkhead against climate change and other environmental perturbations.

Systemic and Nonsystemic Management

Problems arise when ecosystems are managed nonsystemically, for example to maximize production of just one or a few target services to the exclusion and at net cost to other services and the integrity of the productive system (such as intensive agricultural production). As widely observed elsewhere, this has been the fate of wetlands across much of this planet, more commonly the maximization of some traded services (mainly provisioning services) resulting in widespread degradation of wetlands and their capacity to provide a wealth of nontraded (mainly regulatory, cultural, and supporting) services.

Conversely, optimization of wetland management to provide a range of ecosystem services may simultaneously protect or enhance multiple benefits for society. This diversity of benefits may be expressed over a range of scales including global (carbon sequestration stabilizing the climate), national (supporting valued biodiversity and providing amenity and tourism opportunities), catchment (floodwater attenuation and the buffering of river floods), or localized (breaking down heat islands or forming soils).

Systemic Governance

It is well known that “siloed” policies and management actions, addressing narrow goals in isolation, are contributing to the ongoing decline of the quantity and quality of the wetland resource. Wetland protection and functioning, as for other ecosystem resources, are too often treated as “conservation” issues. This anachronistic view posits wetland protection as a restraint to “growth,” ignoring the contribution that wetlands make to society. It also tends to target only protected areas, rather than the wetland functions that occur often in small pockets across wider landscapes.

Systemic management therefore requires a policy base that recognizes and integrates all of the many values potentially provided by wetlands and other ecosystems. Examples include incorporation into relevant policy areas the benefits of wetland functions for air quality enhancement, ameliorating urban and rural flooding, breaking down heat islands, harboring the predators of crop pests, provision of amenity, recreation and educational resources, the production of fiber for fuel, thatch and other economic resources, habitat for fishery recruitment and biodiversity, landscape quality, and the buffering of flows protecting water resources. Policy areas benefitting from these services need to fully integrate the values that wetlands provide, recognizing their dependency on this natural infrastructure and, conversely, their vulnerability if it is lost. Thus, wetland values must necessarily become integrated across all policy areas, rather than as at present commonly regarded by them as constraints on a more technocentric model of development.

A more far-seeing policy-base addressing all of the services provided by wetlands necessarily also requires an economic approach that values them appropriately for inclusion in decision-making and an awareness of the many values of wetlands to different elements of society. Today, inherited siloed perspectives are all too often reinforced by "ring-fenced" budgets within the constraints of single government bodies or directed at only narrowly framed outcomes. Appropriate valuation of ecosystem services, whether in monetary terms or by other means, is then essential if the full importance of ecosystems is to be incorporated into policy-making, economics, and other decision-making systems.

Systemic perspectives, policies, and economics then need to be incorporated into pragmatic operational tools supporting "real world" decision-making, bringing the functions of wetland systems into the mainstream of decision-making by reflecting the multiple values that they provide for all in society. Significant obstacles to the achievement of this goal have yet to be overcome, including, for example, the distribution of benefits and costs of wetland protection including the "profits foregone" of landowners holding back from lucrative practices (such as intensive farming or tree planting) in order to protect publically beneficial ecosystem services (such as floodwater attenuation, carbon sequestration, or support for wildlife). Novel market-based instruments such as "payments for ecosystem services" (PES) may have a role to play here in bridging these gaps.

The human system and its governance remains a major impediment to more sustainable and systemic wetland management. The term "policy resistance" describes the inherent resistance of the establishment to allow changes to affect governance systems; people seem to prefer to live with a familiar but flawed system than to allow changes that might cause uncertainty and instability (Meadows 2008).

Future Challenges

Major challenges are inherent in the legacy of narrowly framed legislation, budgets, and expectations. This is exacerbated by a perception of wetlands either as "wastelands" or else as protected sites that inhibit economic development, when the reality is that wetlands and their services represent important natural capital underpinning future human wellbeing and potential for development. The multiple values of the diverse ecosystem services provided by wetlands benefiting all in society need to be brought into the mainstream of legislation, regulation, market instruments, and societal awareness. Barriers erected by the distribution of benefits and costs of both narrowly exploitative or, conversely, multibenefit management need also to be overcome through the installation of appropriate incentive and reward systems.

This includes recognizing the value of many different types of wetlands distributed across landscapes and not just the relatively few larger wetlands within areas designated as nature conservation priorities.

Finally, "policy resistance" inhibiting societal change needs to be overcome if the benefits of wetland are to be fully recognized and brought into the mainstream of decision-making. Education about and better recognition of the societal values of wetlands may play a major role in this transition.

International Framework for Wetland Conservation and Wise Use

Robert J. McInnes

Framework of International Conventions

49

Royal C. Gardner

Contents

Abstract

A convention is a written agreement between two or more countries that is governed by international law. Such an agreement might be formally called a treaty, convention, protocol, or other name, but the name is not critical. The important point is that the countries that are parties to the agreement intend to be bound by its provisions. The convention most relevant to wetlands is the Convention on Wetlands of International Importance especially as Waterfowl Habitat, which is commonly referred to as the Ramsar Convention.

Convention Basics

A convention is a written agreement between two or more countries that is governed by international law. Such an agreement might be formally called a treaty, convention, protocol, or other name, but the name is not critical. The important point is that the countries that are parties to the agreement intend to be bound by its provisions. The convention most relevant to wetlands is the Convention on Wetlands of International Importance especially as waterfowl habitat which is commonly referred to as the Ramsar Convention (www.ramsar.org).

The text of a convention is developed through negotiations. Since the beginning of the twentieth century, most convention texts have followed a fairly consistent format. The text of a convention typically begins with a preamble describing the contracting parties and their joint objectives in executing the agreement. Often the preamble is structured around a single, long sentence which is formatted into multiple paragraphs to improve readability. Each subsequent paragraph normally begins with a verb (recalling, recognizing, urging, etc.).

The sovereign titles or the full names of the contracting parties are usually included in the preamble, along with the full names and titles of their representatives. Often a standard clause is included to describe how their representatives have communicated (or exchanged) their full powers (i.e., the official documents appointing them to act on behalf of their respective countries) and found them in good or proper form.

After the preamble it is normal for there to be a series of numbered articles. These articles usually contain the substance of the actual agreement into which parties are joining. Each article is usually a single paragraph. In longer convention texts, the articles may be assembled or grouped under specific headings. Modern treaties, regardless of subject matter, normally contain articles governing the deposition of the final authentic copies of the treaty and describing how potential disputes will be resolved.

The end of a treaty, the closing protocol, is normally signaled by a clause like "IN WITNESS WHEREOF, the parties undersigned," followed by the words "DONE at," with details of where the treaty was executed and the date(s) of its execution. The date is typically written in its most formal, longest possible form. For example, the Ramsar Convention states: "DONE at Ramsar this 2nd day of February 1971, in a single original in the English, French, German and Russian languages, all texts being equally authentic which shall be deposited with the Depositary which shall send true copies thereof to all Contracting Parties." If the treaty is executed in multiple copies in different languages, that fact is always noted, as in the case of the Ramsar Convention, and is followed by a stipulation that the versions in different languages are equally authentic.

Bilateral and Multilateral Conventions

A convention between two countries is sometimes referred to as a *bilateral agreement*; a convention with many countries or parties is often called a *multilateral agreement*. Because of their subject matter, some conventions are also known as *multilateral environmental agreements*, or MEAs. Examples of MEAs include the Ramsar Convention; the Kyoto Protocol, which deals with greenhouse gas emissions; and the Basel Convention, which covers the transboundary movement of hazardous wastes. Several MEAs have a biodiversity focus. This cluster of biodiversity-related MEAs have separate but partially overlapping mandates and include:

- Ramsar Convention on Wetlands (Ramsar)
- Bonn Convention on Migratory Species (CMS) and its Agreements
- Convention on International Trade in Endangered Species (CITES)
- World Heritage Convention (WHC)
- Convention on Biological Diversity (CBD)
- International Treaty on Plant Genetic Resources (ITPGR)
- International Plant Protection Convention (IPPC)

Development of a Convention

Conventions can arise as a result of underlying events, such as dispute between states, or with regard to common concern. The development and implementation of a convention can be a lengthy process. For example, in the early 1960s, in light of increasing concerns about losses of wetland habitat and associated declines in waterfowl populations, a number of nongovernmental organizations (NGOs), governments, and wetland and waterbird ecologists recognized the need and potential for an international governmental agreement on wetlands. After over 8 years of discussions, meetings, and negotiations, in 1971 governmental representatives from 18 countries (with observers from other countries, intergovernmental organizations (IGOs), and NGOs also present) met in the Iranian city of Ramsar, on the coast of the Caspian Sea, to seek to finalize the terms of the treaty. Thus, "Ramsar" is not an acronym; the Convention takes its name from the location in which it was negotiated or signed just like the Kyoto Protocol or Basel Convention. On February 2, 1971, the treaty was concluded (i.e., the negotiators agreed on the final form of the text) and it was opened for signature. By its terms, the Ramsar Convention would enter into force (become effective) once seven countries agreed to become parties. The Ramsar Convention entered into force in December 1975. For a full account of the development and early history of the Convention, see Matthews (1993).

Ratification of a Convention

Conventions can be considered as "self-executing," insofar that a party puts the treaty and all its obligations in action upon accession. Other conventions may be non-self-executing and require primary legislation, through a change to domestic law, to fulfill the ascribed obligations. Like many other conventions, the Ramsar Convention text establishes several procedural options for a country to become a Ramsar party. A country can join the treaty either by a notification of accession, signature of the Convention subject to ratification (followed by ratification), or signature without reservation of ratification. Each country becoming a Ramsar party can choose which procedure to follow, according to its own ratification procedures. In the United States, for example, the US Senate must ratify a treaty, approving it by at least a two-thirds vote. The United States became a Ramsar party during the Reagan administration when the US Senate ratified the Ramsar Convention in 1987. Whichever procedure is followed, the notification of joining the Convention must be sent to the United Nations Educational, Scientific, and Cultural Organization, which is the Convention's legal depository organization. The Convention then enters into force in that country 4 months after accession or ratification.

Convention Bodies

Most conventions call for representatives of the parties (and others) to gather and meet at regular intervals to assess progress and exchange information. Often these events are referred to as a *conference of the parties* (COP) or a *meeting of the parties* (MOP). As with any treaty regime, there is a host of different entities that work together to promote a convention's objectives. The COP (or MOP) is typically the primary decision- and policy-making body of a convention. Depending on the convention, actions at such gatherings may be adopted by consensus or by vote. In the Ramsar context, for example, the COP meets every 3 years to assess how the Convention is being implemented and to consider resolutions and recommendations related to wetland conservation. It is a long-upheld Ramsar tradition that COP decisions are made by consensus.

Because decisions must be made and guidance provided between COPs, another important convention entity is the *standing committee*, which may serve as the COP's intersessional governance body. In the Ramsar Convention, the Ramsar COP elects the members of the standing committee on a regional basis, with the number of representative member parties for each Ramsar region being determined by the number of parties in that region.

Most conventions establish a *secretariat* or some other body charged with coordinating the day-to-day activities of the convention. Many MEAs also provide for the establishment of a *scientific advisory body*. These bodies, such as Ramsar's Scientific and Technical Review Panel (STRP) or the Convention on Biological Diversity's Subsidiary Body on Scientific, Technical and Technological Advice (SBSTTA), provide advice and guidance to the conventions, the parties, and other stakeholders.

The Legal Effect of an International Convention

A fundamental principle of international law is *pacta sunt servanda*: promises or agreements must be kept. This principle applies to MEAs such as the Ramsar Convention and its parties. But many MEAs' duties are written in a manner that affords the parties flexibility and discretion in how to implement them. Accordingly, in some cases, such as in the Ramsar Convention context, the obligations are often considered “soft law,” espousing aspirational goals, but not dictating binding legal obligations.

Note the legal effect of a convention within a particular country varies widely. The extent to which a convention or treaty applies directly in a country depends in part on whether that country subscribes to a monist or dualist approach to international law (Bruch 2006). A monist approach generally means that “international law is part of the domestic law of the country” (Bruch 2006). This means in some countries that an international convention is viewed as controlling or overriding domestic or national law. In other monist countries, an international convention has the same authority as a statute or legislative decree, while in other countries domestic laws trump conventions. Despite these variations within monist countries, an important distinction is when such a country joins a convention that agreement “is directly applicable” if its provisions are sufficiently clear. In contrast, countries that have a dualist approach to international law consider international law to be separate from domestic law. Consequently, an international legal instrument, such as the Ramsar Convention, does not immediately affect a dualist country’s domestic legislation. In order for the convention to apply within that jurisdiction, the dualist country would have to enact implementing legislation, also known as the “act of transformation” (Bruch 2006). In very broad terms, civil law countries follow the monist approach, while common law countries use the dualist approach. Some countries, such as the United States and New Zealand, follow a mixed approach (Shelton 2011).

The view that the Ramsar Convention or other MEAs is soft law does not mean, however, that it is without effect on a party’s domestic laws and internal decision-making processes. In some countries, such as Australia, the Ramsar Convention and the designation of sites have been used to augment the national government’s authority over environmental issues (Finlay-Jones 1997). In other countries, Ramsar guidance has prompted the development of comprehensive wetland policies and strategic plans (Bowman 2002; Gardner 2003). A case out of the Netherlands Antilles illustrates that Ramsar resolutions can even affect site-level permitting decisions (Verschuuren 2008).

In 2006, the government of Bonaire, the local authority of the Dutch territory of Netherlands Antilles, authorized a resort to be built adjacent to Het Lac, a Ramsar site. The governor-general annulled the granting of the permit because the environmental impact assessment failed to satisfy the commitments in Resolution VIII.9 adopted by the parties in 2002. Bonaire appealed to the Dutch Crown, contending that Ramsar resolutions are not legally binding. In November 2007 Queen Beatrix issued a royal decree upholding the annulment reasoning that “resolutions, decisions and guidelines accepted unanimously by the Conference of Parties to the Convention, of which the Netherlands is a signatory, must be considered part of the national obligations under the Convention” (Newton 2007).

Not all parties accept the legal theory that consensus-approved resolutions at conferences of the parties create binding domestic obligations. There is case law to the contrary in the United States regarding the Montreal Protocol on Substances that

Deplete the Ozone Layer, for example (NRDC v. EPA 2006). Regardless of whether a convention's resolutions are considered binding law or an expression of goals, they can influence the actions of the parties and other stakeholders.

Future Challenges

International conventions, and especially those in the area of the environment as described by the MEAs, are an important component of global governance and vital mechanism for the protection of natural resources such as wetlands. In the future, compliance with the objectives of these international conventions and agreements will be essential if governments are to deliver on sustainable development and the wise use of wetlands (Gardner and Davidson 2011).

Abstract

Although the Ramsar Convention on Wetlands is the primary multilateral intergovernmental environmental agreement (MEA) addressing inland and coastal wetlands, the scope and mandate of a number of other such MEAs also cover issues relevant to wetland conservation and wise use and the conservation of wetland-dependent species. Efforts are underway to establish ways and means of streamlining multiple conventions' implementation and enhancing synergies. The Ramsar Convention has established bilateral mechanisms for such inter-convention collaboration, which is most well established with the Convention on Biological Diversity (CBD) and the Convention on Migratory Species (CMS). A number of mechanisms have also been established for coordination between the various bodies of the biodiversity cluster of conventions.

Keywords

Ramsar convention · Multilateral environmental agreements (MEAs) · Biodiversity-related conventions · Convention on Biological Diversity (CBD) · Convention on Migratory Species (CMS) · African-Eurasian Migratory Waterbird Agreement (AEWA) · Millennium Ecosystem Assessment · IPBES

Introduction

Whilst the Ramsar Convention on Wetlands is the primary multilateral intergovernmental environmental agreement (MEA) addressing inland and coastal wetlands, the scope of a number of other such MEAs also cover issues relevant to wetland conservation and wise use. The landscape of an increasing number of global (and regional) multilateral environmental agreements (MEAs) – each with different, separately negotiated mandates that overlap to varying degrees – has become more complex over the last two decades. There is increasingly wide recognition of the need to identify ways and means of ensuring that global mechanisms and on-the-ground implementation of multiple biodiversity-related conventions become more consistent, streamlined, and coordinated. There is much ongoing debate within United Nations processes about options for International Environmental Governance (IEG) reform within the United Nations system, and there have been a variety of suggestions for the "clustering" or grouping of biodiversity-related MEAs.

While this debate continues, MEAs have been working together in a variety of practical ways of increasing their cooperation and improving collaborative implementation at global and national levels, including the framework of bilateral memoranda of cooperation and joint work plans and multilateral networks such as the UNEP-initiated Environment Management Group (EMG), the Biodiversity Liaison

Group (BLG) of biodiversity convention secretariats, and the Chairs of the Subsidiary Advisory Bodies of the Biodiversity Conventions (CSAB).

It is generally recognized that the cluster of global biodiversity-related intergovernmental agreements consists of six conventions/agreements, each of which has separate but partially overlapping mandates. These are the:

Ramsar Convention on Wetlands (Ramsar)
Bonn Convention on Migratory Species (CMS) (and its agreements)
Convention on International Trade in Endangered Species (CITES)
World Heritage Convention (WHC)
Convention on Biological Diversity (CBD)
International Treaty on Plant Genetic Resources for Food and Agriculture (ITPGRFA)

This chapter outlines the current state of cooperation (a) bilaterally between other conventions and Ramsar, focusing on CBD, CMS, and WHC, and (b) multilaterally on cooperation and information-sharing mechanisms in the biodiversity convention cluster. The Ramsar Convention is recognized as having been at the forefront of developing and implementing practical mechanisms for achieving such synergies.

Information on the full range of cooperation agreements between Ramsar and other organizations is summarized in Ramsar Convention Secretariat (2012) and supported by texts of memoranda of cooperation and joint work plans.

One major impediment to harmonization and streamlined synergies between MEAs is a lack of communication and consultation at national scale between the respective focal points of each MEA. Although parties to the biodiversity conventions have adopted repeated calls for such national-level coordination, this is not consistently in place. This can, and does, lead to situations where a country has one clear position on an issue in one MEA process, but a different position on the same issue in the process of another MEA, potentially leading to different outcomes in formal MEA COP decisions. This has been particularly marked in recent years in MEA debates on climate change and REDD+ (reducing emissions from deforestation and forest degradation) and on invasive alien species (IAS) and can lead to the same governments agreeing different decisions on the same issues in different MEAs.

Bilateral Cooperation Mechanisms on Wetlands in the Biodiversity Cluster of Conventions

The Convention on Biological Diversity (CBD) (http://www.cbd.int/)

Cooperation between Ramsar and CBD is the most well established and developed of such convention collaborations on biodiversity and is recognized as a model for how such streamlining can be done under existing multi-convention arrangements, recognizing that each MEA has distinct but overlapping scope and mandate (Davidson and Coates 2011). It has developed progressively and incrementally over the last 20 years.

The Ramsar–CBD partnership began with a Memorandum of Cooperation in January 1996 and in the same year with the CBD's recognition by its contracting parties (governments) of the Ramsar Convention as its "lead implementation partner" on wetlands (CBD Decision III/21), i.e., implementation across the scope of Ramsar's wetland coverage of inland, coastal, and human-made wetlands. Thus, implementation of the commitments under the Ramsar Convention is simultaneously an implementation of CBD commitments across the range of its thematic and crosscutting programs of work, including the ecosystem approach, for wetlands (see Finlayson et al. 2011 for discussion of the relationships between the CBD "ecosystem approach" and Ramsar's "wise use" of wetlands).

Subsequently, collaborative implementation has been guided by five successive Joint Work Plans, from 1998 onward, and with the current fifth plan being for 2011–2020, the updating of the Memorandum of Cooperation in 2005, and repeated recognition of the importance of such collaboration between MEAs in successive CBD COP decisions and Ramsar COP Resolutions.

Collaboration has moved from these affirmations of common interest, through recommending or adopting guidance prepared by one convention for use by the other, such as CBD's impact assessment guidelines adopted by Ramsar with interpretation for their application in the Ramsar context, to joint review and development of programs and guidance. Examples include joint preparation and publication of technical reports requested by parties and Ramsar's lead in undertaking the 2010 review and revision of the CBD program of work in the biological diversity of inland waters, which provided the basis for the adoption of CBD COP10 Resolution X/28 on inland water biodiversity.

Other recent areas of work requested of Ramsar by the CBD include further development of criteria for identifying sites of international importance for wetland biodiversity (cf. Ramsar Site designation criteria) and developing a framework for joint reporting on inland waters and other wetlands. For the latter, this already has been largely achieved through the parallel development of complementary national reporting formats by the two conventions. Ramsar's format largely concerns implementation process reporting while the CBD's national reports largely require ecological outcome reporting in relation to achievements toward the 2010 biodiversity target and now the 2020 Aichi Biodiversity targets.

In addition, CBD's COP10 (2010) decision on inland waters biodiversity invited the Ramsar Secretariat and its Scientific & Technical Review Panel (STRP), working with the CBD Secretariat, to establish an expert working group to review available information and provide key policy relevant messages, on maintaining the ability of biodiversity to continue to support the water cycle – work which is currently underway as a major assessment of the roles of different ecosystems in the water cycle.

The same decision also requested the CBD Secretariat to analyze information in the CBD's Fourth National Reports on the status and trends of wetlands and drivers of change in wetlands to strengthen mutual information flow between the two conventions and to inform the planned Ramsar "state of the world's wetlands" report.

However, despite these significant areas of collaboration, there continue to be several constraints and limitations in the extent of the Ramsar–CBD cooperation achieved to date and prospects for the future.

First, most achievements have so far been at the global scale, through the collaborative work of the secretariats and the conventions' scientific and technical subsidiary advisory bodies (Ramsar's STRP and the CBD's Subsidiary Body on Scientific, Technical and Technological Advice (SBSTTA)). Although called for in both CBD and Ramsar's decisions on collaboration between conventions, there has been much less consistency in the extent of national-scale communication and collaborative implementation including between the conventions' respective national focal points. This in turn has been recognized as a key precondition to establish harmonized national reporting, as has been repeatedly called for in discussions on synergies UNEP-WCMC 2009).

Second, and despite the terms of CBD Decision III/21, CBD parties and their decisions have subsequently focused on Ramsar collaboration mainly in the context of only the CBD program of work on inland waters. CBD parties, in their separate development and adoption of their other biome and crosscutting programs of work, have largely ignored the relevant implementation role of Ramsar, notably in coastal and nearshore marine systems (with Ramsar coverage extending across the whole coastal zone to a depth of 6 m of permanent inundation) and in protected areas in relation to the designation and management of Wetlands of International Importance (Ramsar Sites). CBD COP10 (2010) finally gave some recognition to the relevance of Ramsar's lead implementation role for these matters, in its protected areas and marine and coastal biodiversity programs of work. However, these and other CBD programs of work continue to pay little attention to Ramsar's long-standing implementation experience on such matters.

Third, until very recently, and at least in part due to inadequate adoption of ecosystem approaches, CBD processes and decisions have failed to recognize the crucial and crosscutting relevance of water and water management if there is to be any chance of achieving successful biodiversity conservation. This includes not just managing water to maintain ecosystems (including wetlands) but also the key role that wetlands and other ecosystems play as the natural infrastructure which maintains the water cycle and so provides water security for both ecosystems and people and the delivery of most ecosystem benefits, including the many needs and uses of water which are central to human welfare.

These issues are at the core of the Ramsar Convention's text and are a major focus of its implementation, particularly since 1996 and the adoption of Resolution VI.23 on *Ramsar and Water*. This was to some extent recognized at CBD COP10 in

October 2010, particularly in its Decision X/28 on inland water biodiversity, but also in the *Strategic Plan for Biodiversity 2011–2020*, which recognized the paramount importance of water as an ecosystem service. This now lays an improved framework, facilitating enhanced collaboration among all the biodiversity MEAs, which have all committed to supporting implementation of this strategic plan. The improved recognition of water as an ecosystem service also significantly increases resonance between the *Strategic Plan for Biodiversity*, and hence the MEAs, and the significant broader social, economic, and political interest in water.

Convention on Migratory Species (CMS) (http://www.cms.int/)

The CMS mandate covers all taxa of species which are regarded as migratory, under a geopolitical definition of "Migratory species" which regularly cross national boundaries on a regular and predictable basis: "Migratory species" means the entire population or any geographically separate part of the population of any species or lower taxon of wild animals, a significant proportion of whose members cyclically and predictably cross one or more national jurisdictional boundaries" (CMS text Article 1.1 a).

The Ramsar Secretariat and the CMS Secretariat first signed a memorandum of understanding in February 1997. It sought to ensure cooperation between the two secretariats in the fields of joint promotion of the two conventions; joint conservation action; data collection, storage, and analysis; and new agreements on migratory species, including endangered migratory species and species with an unfavorable conservation status. This was renewed as a Memorandum of Cooperation (MoC) in 2012. This renewed MoC makes provision for all relevant CMS daughter agreements and memoranda to develop bilateral Joint Work Plans with Ramsar, under the framework of the MoC, although no such further plans have yet been concluded.

A three-way Joint Work Plan between the secretariats of the CMS, the African-Eurasian Migratory Waterbird Agreement (AEWA), and the Ramsar Convention was signed in April 2004. A subsequent second Joint Work Plan (2012–2014) between Ramsar and CMS only was agreed between the secretariats in 2012.

Recent areas of collaborative implementation activity are summarized in CMS Secretariat (2011). These have included:

- Joint participation in the Task Forces on Avian Influenza and Wildlife Diseases
- Development of policy for migratory flyway conservation (see, e.g., Global Interflyway Network 2012)
- Participation by CMS in Ramsar's Regional Strategy for the Conservation and Sustainable Use of High Andean Wetlands
- Joint Ramsar Advisory Missions (RAM) to Ramsar Sites under threat which are important for migratory waterbirds

There a number of agreements and memoranda established through the CMS which are directly relevant to the conservation and wise use of migratory wetland-dependent species of fish, birds, and mammals and whose implementation contributes also to Ramsar goals and strategies. These include:

Agreements

- Wadden Sea Seal Agreement
- Agreement on the Conservation of Cetaceans in the Black Sea, Mediterranean Sea and Contiguous Atlantic Area (ACCOBAMS)
- Agreement on the Conservation of Small Cetaceans in the Baltic, North East Atlantic, Irish and North Seas (ASCOBANS)
- African-Eurasian Migratory Waterbird Agreement (AEWA)
- Agreement on the Conservation of Albatrosses and Petrels (ACAP)
- Agreement on the Conservation of Gorillas and Their Habitats

Memoranda of Understanding

- Conservation Measures for the Aquatic Warbler (*Acrocephalus paludicola*)
- Conservation Measures for the Siberian Crane
- Conservation and Management of Marine Turtles and Their Habitats of the Indian Ocean and South-East Asia (IOSEA)
- Conservation Measures for Marine Turtles of the Atlantic Coast of Africa
- Conservation of High Andean Flamingos and Their Habitats
- Conservation Measures for the Eastern Atlantic Populations of the Mediterranean Monk Seal (*Monachus monachus*)
- Conservation of Cetaceans and their Habitats in the Pacific Islands Region
- Conservation Measures for the Slender-Billed Curlew
- Conservation of the Manatee and Small Cetaceans of Western Africa and Macaronesia
- Conservation Measures for the Ruddy-Headed Goose (*Chloephaga rubidiceps*) (between the Argentine Republic and the Republic of Chile)
- Conservation of Migratory Sharks
- Conservation Measures for the West African Populations of the African Elephant (*Loxodonta africana*)

For more information on each of these agreements and memoranda, see the CMS Family Portal on: http://www.migratoryspecies.org/.

For most of these agreements and memoranda, there are not yet any formally established cooperation mechanisms with the Ramsar Convention. The most well-established cooperation is between Ramsar and AEWA (http://www.unep-aewa.org/). All species covered by AEWA are "wetland dependent" and so also covered by the provisions of the Ramsar Convention and Ramsar's established mechanisms such as for international waterbird flyway cooperation, and the designation of Ramsar Sites for waterbirds also supports AEWA implementation.

A major collaborative project between AEWA, Ramsar, BirdLife International, and Wetlands International on African-Eurasian migratory waterbird flyways – the "Wings over Wetlands (WOW) UNEP-GEF African-Eurasian Flyways Project" – was successfully completed in 2010 and was designed to increase knowledge and capacity for flyway-scale waterbird conservation throughout the region. Its outputs include an online Critical Site Network (CSN) tool, the establishment of regional training centers, and a comprehensive flyways training kit. For further information and access to these tools, see: http://www.wingsoverwetlands.org/.

At the conclusion of the project, the four main project partners agreed to continue their collaboration to develop a follow-on programmatic partnership based on the *WOW Project* for flyway-scale conservation of migratory waterbirds and the wise use of wetlands and signed a Memorandum of Cooperation (MoC) on the "Partnership for the Conservation of Migratory Waterbirds and their Habitats (Wings Over Wetlands)," during the AEWA 15th Anniversary Symposium in The Hague, the Netherlands, in June 2010.

AEWA's 5th Meeting of the Parties (MOP5) in 2012 strongly recognized the important role that implementing Ramsar mechanisms contributes to AEWA (see AEWA 2012a, b) and in particular the role that designating a comprehensive network of Ramsar Sites for migratory waterbirds can support flyway-scale conservation.

The World Heritage Convention (WHC) (http://whc.unesco.org/)

A considerable number of World Heritage Sites inscribed under the World Heritage Convention (both "natural" sites and mixed "natural/cultural" sites) are or include wetlands. Ramsar is consulted (through IUCN in their capacity as advisors to the World Heritage Committee on natural sites) on any new World Heritage Site nominations by governments and which include coastal or inland wetlands.

A memorandum of understanding was signed between the Ramsar Secretariat and the World Heritage Centre in May 1999. The Ramsar Secretariat and the World Heritage officer in charge of natural sites maintain a close working relationship with a view to:

- Promoting nominations of wetland sites under the two conventions
- Reviewing reporting formats and coordinating the reporting about shared sites
- Contributing to both conventions' training efforts
- Coordinating fundraising initiatives concerning shared sites
- Encouraging the establishment of joint national committees

World Heritage and Ramsar have also worked closely on joint expert advisory missions in recent years to a number of joint sites, including Ichkeul (Tunisia), Djoudj and Diawling (Senegal and Mauritania), and Lake Srebarna (Bulgaria). The two conventions maintain a list of wetland sites common to World Heritage and Ramsar.

There are, however, some continuing disconnects between the WHC and Ramsar mechanisms which could be valuably closed in terms of improving synergies. These include that:

- Not all wetland WH Sites have also been designated as Ramsar Sites, an example being Australia's Great Barrier Reef World Heritage Site which also wholly qualifies also for Ramsar Site designation
- The placing by the WHC of a site on the list of "World Heritage Sites in Danger" does not necessarily mean that the same government also invokes Article 3.2 reporting under the Ramsar Convention, which it should. Conversely, a Ramsar Party making an Article 3.2 report for a joint Ramsar/World Heritage Site does not always lead to consideration by the WHC of placing the site also on the WH Sites in Danger List.

The Convention on International Trade in Endangered Species (CITES) (http://www.cites.org/)

A considerable number of globally threatened plant and animal species covered by The Convention on International Trade in Endangered Species (CITES) the mandate of CITES are wetland dependent, for example, some tropical peat swamp forest trees, dugong and manatees, sturgeon, and many species of globally threatened waterbirds. Thus, CITES actions and decisions to control international trade in such species directly contribute to the conservation of wetlands and their ecological character at the species level. However, there are not as yet any formal cooperation agreements in place between Ramsar and CITES processes.

The International Treaty on Plant Genetic Resources for Food and Agriculture (ITPGRFA) (http://www.planttreaty.org/)

The 2001 International Treaty on Plant Genetic Resources for Food and Agriculture aims at:

- Recognizing the enormous contribution of farmers to the diversity of crops that feed the world
- Establishing a global system to provide farmers, plant breeders, and scientists with access to plant genetic materials
- Ensuring that recipients share benefits they derive from the use of these genetic materials with the countries where they have been originated

The treaty's work is relevant to the Ramsar Convention particularly in relation to the maintenance of the ecological character of the many wetlands, including Ramsar Sites, which are used for agriculture, and the coverage under Ramsar of human-made wetlands, notably rice paddies. There are not as yet any formal cooperation agreements in place between Ramsar and the ITPGR. However, there a formal cooperation agreements between FAO (which hosts ITPGR) and the International Water Management Institute (IWMI, which is a formal Ramsar International Organisation Partner (IOP)) which could potentially support ITPGR and Ramsar collaborations.

Other Conventions and Agreements Relevant to Wetlands

United Nations Convention to Combat Desertification (UNCCD) (http://www.unccd.int/en/Pages/default.aspx)

Although not formally treated as part of the biodiversity cluster of MEAs, there is considerable complementarity between UNCCD and Ramsar. While wetlands are crucially important everywhere, they are even more vital in arid and semi-arid lands. The Ramsar Secretariat was present at the first UNCCD Conference of the Parties in October 1997, where it distributed to the delegates an information document on "Wetlands in Arid Zones." In December 1998, during the second UNCCD Conference of the Parties, the secretary-general of the Ramsar Convention and the Executive Secretary of the CCD signed a Memorandum of Cooperation between the secretariats to help increase communication between them, coordinate efforts, and avoid duplication. Subsequent practical cooperation between the secretariats has focused on common issues in Africa but has been developing only slowly so far.

The International Whaling Commission (IWC) (http://iwc.int/home)

The International Whaling Commission (IWC) was set up under the International Convention for the Regulation of Whaling which was signed in Washington, DC, on 2 December 1946. The preamble to the convention states that its intention is to provide for the proper conservation of whale stocks and thus make possible the orderly development of the whaling industry.

The main duty of the IWC is to keep under review and revise as necessary the measures laid down in the Schedule to the Convention which govern the conduct of whaling throughout the world. These measures, among other things, provide for the complete protection of certain species, designate specified areas as whale sanctuaries, set limits on the numbers and size of whales which may be taken, prescribe open and closed seasons and areas for whaling, and prohibit the capture of suckling calves and female whales accompanied by calves. The compilation of catch reports and other statistical and biological records is also required. In addition, the commission coordinates and funds conservation work on many species of cetaceans. This includes work to reduce the frequency of ship strikes, to coordinate disentanglement events, and to establish Conservation Management Plans for key species and populations.

Many species of cetaceans (great whales) covered by the IWC depend on coastal wetlands (sensu Ramsar) at different stages of their migrations and lifecycles, and so decisions by the IWC can affect Ramsar interests and commitments. However, to date Ramsar has not been involved in IWC processes, and there is opportunity for developing synergies between the two instruments.

The Antarctic Treaty (http://www.ats.aq/index_e.htm)

The conservation of Antarctic wetlands is a special case. The Antarctic Treaty and related agreements, collectively known as the Antarctic Treaty System (ATS), regulate international relations with respect to Antarctica. For the purposes of the treaty system, Antarctica is defined as all of the land and ice shelves south of 60°S latitude. The treaty, entered into force in 1961 and currently having 50 parties, sets aside Antarctica as a scientific preserve, establishes freedom of scientific investigation, and bans military activity on that continent.

Antarctic agreements relevant to the conservation and wise use of wetlands and wetland-dependent species include:

- Agreed Measures for the Conservation of Antarctic Fauna and Flora
- The Convention for the Conservation of Antarctic Seals
- The Convention for the Conservation of Antarctic Marine Living Resources (CCAMLR)

The Protocol on Environmental Protection to the Antarctic Treaty prevents development and provides for the protection of the Antarctic environment through five specific annexes on marine pollution, fauna and flora, environmental impact assessments, waste management, and protected areas.

Annex 5, on protected areas, of the Protocol on Environmental Protection provides that "Any area, including any marine area, may be designated as an Antarctic Specially Protected Area to protect outstanding environmental, scientific, historic, aesthetic or wilderness values, any combination of those values, or ongoing or planned scientific research."

There are currently 71 Antarctic Specially Protected Areas, many of which have been designated for their importance to wetland-dependent species covered by the Ramsar Convention, such as penguins, and mammals, such as seals.

Under the Antarctic Treaty, the Antarctic is not the sovereign territory of any one country but rather as a shared resource. There has been considerable debate in Ramsar as to whether this means that Ramsar Sites can, or cannot, be designated in Antarctica, since Article 4.1 of the convention text provides for designation only within the sovereign territory of a contracting party. This matter was debated at Ramsar COP9 in 2005 following the submission by the government of Switzerland of a draft resolution on designating Ramsar Sites in Antarctica. At that time, parties upheld the view that Ramsar Sites could not be designated in Antarctica, and the draft resolution was withdrawn.

However, this debate continues, with consideration of whether such designations could be made under the convention provisions of Article 5 on international cooperation.

Arctic Council/Conservation of Arctic Flora and Fauna (CAFF) (http://www.caff.is/)

The activities of the Arctic Council of ministers are conducted through six working groups, one of which is on the Conservation of Arctic Flora and Fauna (CAFF). CAFF's activities include the Circumpolar Biodiversity Monitoring Program (CBMP) – an international network of scientists, governments, indigenous organizations, and conservation groups working to harmonize and integrate efforts to monitor the Arctic's living resources, and the preparation of the periodic *Arctic Biodiversity Assessment*, the most recent being CAFF (2013).

Since the Arctic is of major importance for its wetlands, and crucial for the breeding and survival of Arctic wetland-dependent birds (notably migratory waterbirds) and mammals such as seals, walrus, and cetaceans, there is much common ground between CAFF and Ramsar. In recognition of this, the CAFF and Ramsar signed a Resolution on Cooperation (ROC) during Ramsar COP11 in 2012. The ROC recognizes the mutual importance of Arctic wetlands to both organizations and highlights potential opportunities to collectively build and share knowledge, create awareness, and enhance capacity for understanding change in these important ecosystems.

Multilateral Cooperation Mechanisms in the Biodiversity Cluster of Conventions

The Environment Management Group (EMG) (http://www.unemg.org/)

The EMG is a United Nations (UN) system-wide coordination body on environment and human settlements. It was established in 2001 through UN General Assembly resolution 53/242 in July 1999. The EMG membership consists of the specialized agencies, programs, and organs of the United Nations including the secretariats of the multilateral environmental agreements. Although the Ramsar Convention Secretariat is not UN administered, given that the convention itself is a UN-recognized treaty, Ramsar participates fully in the EMG.

The group is chaired by the Executive Director of United Nations Environment Programme (UNEP) and supported by a secretariat provided by UNEP. The secretariat is located in Geneva, Switzerland. The EMG identifies issues on the international environmental agenda that warrant cooperation and finds ways of engaging its collective capacity in coherent management responses to those issues. The EMG works through technical meetings, Issue Management Groups, and task forces. Representatives of intergovernmental bodies, civil society, and international nongovernmental organizations can be invited to contribute.

Liaison Group of Biodiversity-Related Conventions (BLG) (http://www.cbd.int/blg/)

The Liaison Group of Biodiversity-Related Conventions (BLG) meets regularly to explore opportunities for synergistic activities and increased coordination and to exchange information. Meetings involve the senior secretariat officials of each convention.

The mandate for establishing the Liaison Group of Biodiversity-Related Conventions was set out by the Parties to the CBD, in CBD COP7 Decision VII/26. Subsequently, through CBD COP9 Decision IX/27, CBD Parties underlined the important role of the Liaison Group of Biodiversity-Related Conventions, encouraged more regular meetings, and invited the group to identify options for improved implementation of and cooperation among biodiversity-related conventions.

Furthermore, through CBD COP10 Decision X/20, the Conference of the Parties to the CBD further underlined the need for strengthened effectiveness and improved harmonization of the biodiversity-related conventions. Paragraph 11(a) requested the biodiversity-related convention to review and, where necessary, update working arrangements, and at the Second Retreat of Biodiversity-Related Conventions held in Geneva on 4 September 2011, a new *modus operandi* was agreed and signed by all six biodiversity-related conventions.

Chairs of the Scientific Advisory Bodies of the Biodiversity-Related Conventions (CSAB) (http://www.cbd.int/csab/)

In 2006, the fifth meeting of the Liaison Group of the Biodiversity-Related Conventions (BLG) considered ways to strengthen the cooperation among the scientific advisory bodies of the Biodiversity-Related Conventions and to further improve the scientific advice available to these bodies. The BLG agreed to call a meeting of chairs of the scientific and technical bodies or advisory bodies of the conventions, together with representatives of the Convention Secretariats, the GEF Scientific and Technical Advisory Panel (STAP), and the United Nations Environment Programme (UNEP).

This first meeting of the CSAB took place in Paris in July 2007. The CSAB has convened a further five times, its most recent meeting being in October 2013. CSAB meetings generally take place associated with a meeting of the scientific advisory body of one or other of the conventions. Ramsar is represented in CSAB meetings by the chair of its Scientific & Technical Review Panel (STRP).

CSAB has considered a range of scientific and technical issues and topics of common relevance to the biodiversity-related conventions, with a view to ensuring improved consistency of the presentation of such matters to each convention and avoiding duplication of effort. These have included:

- Cooperation on climate change and biodiversity
- The 2010 Biodiversity Target and a coordinated approach for the work beyond 2010
- The Strategic Plan for Biodiversity 2011–2020 and the Aichi Biodiversity Targets
- Management of information and knowledge
- Complementarities and gaps in scientific and technical guidance developed under the conventions
- A multi-convention collaboration on ecosystem restoration
- The role of convention scientific advisory bodies in the Intergovernmental Science-Policy Platform on Biodiversity and Ecosystem Services (IPBES)
- Harmonization of species nomenclature

United Nations Information Portal on Multilateral Environmental Agreements (InforMEA) (http://www.informea.org/)

The MEA Information and Knowledge Management (IKM) Initiative brings together Multilateral Environmental Agreements (MEA) to develop harmonized and interoperable information systems for the benefit of parties and the environment community at large. The initiative is facilitated by the United Nations Environment Programme (UNEP).

InforMEA is an MEA IKM initiative which is designed to enhance web-based access to information about, and decisions made by, all multilateral environmental agreements, including the biodiversity cluster of conventions.

InforMEA harvests COP decisions and resolutions, news, events, MEA membership, national focal points, national reports, and implementation plans from MEA secretariats and organizes this information around a set of agreed terms.

The MEA IKM initiative currently includes 43 international and regional legally binding instruments from 18 secretariats hosted by three UN organizations and the International Union for Conservation of Nature (IUCN). The initiative invites and welcomes the participation of observers involved with MEA data and information, such as the Environment Management Group (EMG), the European Environment Agency (EEA), the Food and Agriculture Organization of the United Nations (FAO), the IUCN, the UNEP-World Conservation Monitoring Centre (UNEP-WCMC), and the International Institute for Sustainable Development (IISD).

Ramsar has been closely involved in the MEA IKM Initiative since its inception and has been working to ensure that InforMEA includes access to all relevant Ramsar materials. However, owing to compatibility issues with the structure of the Ramsar Convention website, not all such information about Ramsar is currently accessible through InforMEA. The recent redevelopment of the Ramsar Convention website is anticipated to resolve this.

UN-Water (http://www.unwater.org/)

UN-Water is the United Nations interagency coordination mechanism for all freshwater- and sanitation-related matters. UN-Water was formalized in 2003 by the United Nations High Level Committee on Programmes. It provides the platform to address the crosscutting nature of water and maximize system-wide coordinated action and coherence. UN-Water promotes coherence in, and coordination of, UN system actions aimed at the implementation of the agenda defined by the Millennium Declaration and the World Summit on Sustainable Development as it relates to its scope of work. Through UN-Water the United Nations acts as "One UN."

The scope of UN-Water's work encompasses all aspects of freshwater, including surface and groundwater resources and the interface between fresh- and seawater. It includes:

- Freshwater resources – both in terms of their quality and quantity, development, assessment, management, monitoring, and use (e.g., domestic uses, agriculture, and ecosystem requirements)
- Sanitation – both access to and use of sanitation by populations and the interactions between sanitation and freshwater
- Water-related disasters, emergencies, and other extreme events and their impact on human security

The main purpose of UN-Water is to complement and add value to existing programs and projects by facilitating synergies and joint efforts, so as to maximize system-wide coordinated action and coherence as well as effectiveness of the support provided to member states in their efforts toward achieving time-bound goals, targets, and actions related to its scope of work as agreed by the international community, particularly those contained in the Millennium Development Goals and the Johannesburg Plan of Implementation (World Summit on Sustainable Development).

UN-Water full members are only UN entities, including those responsible for major funds and programs, specialized agencies, regional commissions, conventions, etc. Other organizations outside of the UN system are partners of UN-Water. Unlike Ramsar's full participation in the UN Environment Management Group (EMG), the Ramsar Convention is treated only as a UN-Water partner, which considerably limits the convention's ability to contribute its expertise on wetlands and water fully to UN-Water processes.

UN-Water coordinates, through its World Water Assessment Programme (WWAP), the preparation of the now annual and thematic "World Water Development Report" (WWDR) that focuses on different strategic water issues each year and aims to provide decision-makers with the tools to implement sustainable use of our water resources. It also includes regional aspects, hotspots, examples, and stories, making the report relevant to a broad range of readers, at different levels and in different geographical areas. The most recent edition, WWDR5 focused on "Water and Energy" (WWAP 2014), WWDR6 on "Water for a Sustainable World" (WWAP 2015) and WWDR6 on "Water and Jobs" (WWAP 2016). Future WWDRs will include in 2017 "Wastewater: the untapped resource" and, of particular relevance to the Ramsar Convention, in 2018 "Nature-based solutions for water".

The Millennium Ecosystem Assessment (MA) (http://www.millenniumassessment.org/en/index.html)

The Millennium Ecosystem Assessment (MA) was called for by the United Nations Secretary-General Kofi Annan in 2000. Initiated in 2001, the objective of the MA was to assess the consequences of ecosystem change for human well-being and the scientific basis for action needed to enhance the conservation and sustainable use of those systems and their contribution to human well-being. The MA involved the work of more than 1,360 experts worldwide. Their findings, contained in five technical volumes and six synthesis reports, provide a state-of-the-art scientific appraisal of the condition and trends in the world's ecosystems and the services they provide (such as clean water, food, forest products, flood control, and natural resources) and the options to restore, conserve, or enhance the sustainable use of ecosystems.

The authorizing environment for the MA was then primarily through the biodiversity-related conventions and in particular the Ramsar Convention, the CBD, and the UNCCD. Ramsar experts were closely involved throughout the MA process, in its design, its governance, and lead expert contributions to its reports.

This resulted in the production by the MA of several "synthesis reports," each targeted at different convention audiences, including:

- Ecosystem Services and Human Well-Being: Wetlands and Water Synthesis (for Ramsar) (http://www.millenniumassessment.org/documents/document.358.aspx.pdf)
- Ecosystems and Human Well-Being: Biodiversity Synthesis (for CBD) http://www.millenniumassessment.org/documents/document.354.aspx.pdf
- Ecosystems and Human Well-Being: Desertification Synthesis (for UNCCD) (http://www.millenniumassessment.org/documents/document.355.aspx.pdf)

The MA's codification of "ecosystem services" (defined as the benefits nature provides to humankind) has been particularly relevance to Ramsar processes and adopted guidance. It has led to the adoption of a redefinition of the Ramsar terms of "wise use" and the "ecological character of wetlands" (Ramsar Convention 2005) and formed the basis for the ecosystem service components of describing ecological character (Ramsar Convention 2008) and those parts of the Information Sheet on Ramsar Wetlands (RIS) – 2012 revision concerning the ecosystem services delivered by Ramsar Sites (Ramsar Convention 2012).

Intergovernmental Science-Policy Platform on Biodiversity and Ecosystem Services (IPBES) (http://www.ipbes.net/)

IPBES was established in April 2012, as an independent intergovernmental body open to all member countries of the United Nations. The members are committed to building IPBES as the leading intergovernmental body for assessing the state of the planet's biodiversity, its ecosystems, and the essential services they provide to society.

IPBES provides a mechanism recognized by both the scientific and policy communities to synthesize, review, assess, and critically evaluate relevant information and knowledge generated worldwide by governments, academia, scientific organizations, nongovernmental organizations, and indigenous communities. This involves a credible group of experts in conducting assessments of such information and knowledge in a transparent way. IPBES is unique in that it will aim to strengthen capacity for the effective use of science in decision-making at all levels. IPBES will also aim to address the needs of Multilateral Environmental Agreements that are related to biodiversity and ecosystem services and build on existing processes ensuring synergy and complementarities in each other's work.

The Ramsar Convention (Secretariat and Scientific & Technical Review Panel) has been closely involved in IPBES processes since its inception in 2008, including its design and the development of its work program. The chair of the STRP participates fully in the IPBES Multidisciplinary Expert Panel (MEP), which also includes members who are also appointed members of the STRP.

IPBES is currently implementing the first phases of its work program, which includes several assessments directly relevant to Ramsar issues. These include thematic assessments on:

- Pollinators, pollination, and food production
- Land degradation and restoration
- Invasive alien species and their control
- Sustainable use and conservation of biodiversity and strengthening capacities and tools

Ramsar Convention on Wetlands: Scope and Implementation

51

Nick C. Davidson

Contents

Abstract

The Ramsar Convention on Wetlands is the longest established of the modern global intergovernmental environmental agreements (often known as multilateral environmental agreements (MEAs)). The text of the Convention was opened for signature in the town of Ramsar, Islamic Republic of Iran, on 2 February 1971. The Convention was developed in the 1960s as a response to increasing concerns about accelerating conversion and destruction of wetlands and the impact of this on both people and biodiversity, especially waterbirds. The Convention's aim is to "stem the progressive encroachment on and loss of wetlands now and in the future," and it expresses its Contracting Parties' confidence "that the conservation of wetlands and their flora and fauna can be ensured by combining far-sighted national policies with coordinated international action." The Convention is implemented through the three "pillars" of its strategic plan: the wise use of all wetlands, the designation and management of Wetlands of International Importance (Ramsar sites), and inter-national cooperation – including on shared wetlands, river basins, and populations of migratory waterbirds. The 45-year growth of the Convention is outlined, as are the Convention's bodies and

The Ramsar Convention on Wetlands

For further information about the Ramsar Convention, see *The Ramsar Manual* (Ramsar Convention Secretariat 2013) and the Convention's web site on www.ramsar.org. Parts of this article are derived from Gardner and Davidson (2011) and Finlayson et al. (2013).

The Ramsar Convention on Wetlands is the longest established of the modern global intergovernmental environmental agreements (often known as multilateral environmental agreements (MEAs)). The text of the Convention was opened for signature in the town of Ramsar, Islamic Republic of Iran, on 2 February 1971. Its full title is "the Convention on Wetlands of International Importance especially as Waterfowl Habitat" (UN Treaty Series No. 14583). The present text of the Convention, as subsequently amended by the Paris Protocol (1982) and the Regina Amendments (1987), is available on http://www.ramsar.org/sites/default/files/documents/library/current_convention_text_e.pdf. The United Nations Educational, Scientific and Cultural Organization (UNESCO) acts as the legal depositary of the Convention.

The Convention was developed in the 1960s as a response to increasing concerns about accelerating conversion and destruction of wetlands and the impact of this on both people and biodiversity, especially waterbirds. The origins and early history and evolution of the Convention are well described in Matthews (1993), and a summary of the Convention's history and progress on the occasion of its 40th anniversary is provided by Ramsar Convention Secretariat (2011).

The Convention's aim is to "stem the progressive encroachment on and loss of wetlands now and in the future," and it expresses the parties' confidence "that the conservation of wetlands and their flora and fauna can be ensured by combining far-sighted national policies with coordinated international action." Those responsible for drafting the Convention text were inspirational and farsighted: the adopted text recognized "the interdependence of Man and his environment"; "the fundamental ecological functions of wetlands as regulators of water regimes and as habitats supporting a characteristic flora and fauna, especially waterfowl"; and "that wetlands constitute a resource of great economic, cultural, scientific, and recreational value, the loss of which would be irreparable," the last being recently affirmed by Russi et al. (2013) in respect of the high economic values of many inland and coastal wetlands. Given the continuing conversion and loss of many wetlands worldwide, these are issues which remain as pertinent today as they were over 40 years ago.

The Convention's Mission, established in its strategic plan (for the fourth strategic plan, for 2016–2024, see Ramsar Convention 2015), is the "conservation and wise use of all wetlands through local and national actions and international cooperation, as a contribution towards achieving sustainable development throughout the world." The strategic plan recognizes that to achieve this Mission, it is essential that vital ecosystem services, and especially those related to water and those that wetlands provide to people and nature through their natural infrastructure, are fully recognized, maintained, restored, and wisely used.

The Convention is implemented through the three "pillars" of the strategic plan (Ramsar Convention 2012): the wise use of all wetlands, the designation and management of Wetlands of International Importance (Ramsar sites), and international cooperation – including on shared wetlands, river basins, and populations of migratory waterbirds.

In 2005 the Convention redefined the wise use of wetlands as "the maintenance of their ecological character, achieved through the implementation of ecosystem approaches, within the context of sustainable development" (Ramsar Convention 2005; Finlayson et al. 2011). In turn, the ecological character of wetlands is "the combination of the ecosystem components, processes and benefits/services that characterize the wetland at a given point in time." This definition notes that within this context, ecosystem benefits are defined in accordance with the Millennium Ecosystem Assessment definition of ecosystem services as "the benefits that people receive from ecosystems" (Millennium Ecosystem Assessment 2003).

The Convention adopted a broad and inclusive definition of wetlands ranging from the mountains to the sea, covering all inland wetlands (including lakes and rivers), coastal and nearshore marine wetlands (including estuaries, mangroves, salt marshes, sea grass beds, and coral reefs) and human-made wetlands (including reservoirs, fishponds, and rice paddies). For the full range of wetland types covered under the Convention, see Ramsar Convention Secretariat (2010). The Convention's coverage of coastal and marine wetlands extends to those permanently inundated to a depth of six meters, so the Convention does not address deep-ocean ecosystems.

Convention Bodies

The Convention is governed by its government contracting parties, who meet every 3 years in a meeting of the Conference of the Contracting Parties (COP). The most recent meeting was COP12 in Uruguay in 2015. At each COP, contracting parties negotiate and adopt Resolutions which set the financial, policy, and technical implementation agenda and priorities for the subsequent triennium.

Intersessionally, Convention implementation is overseen on behalf of all contracting parties by the Standing Committee, composed of representative contracting parties appointed by the COP on a pro rata basis from each of the six Ramsar geopolitical regions (Africa, Asia, Europe, Neotropics, North America, and Oceania – see Ramsar Convention 2012). The Standing Committee meets approximately annually and takes decisions concerning the intersessional use of budgets and implementation and oversees and guides preparations for the COP.

The Scientific and Technical Review Panel (STRP), established in 1993, is the Convention's subsidiary body charged with preparing scientific and technical implementation advice and guidance at the request of the COP. At its core are (COP12 Resolution XII.5 http://www.ramsar.org/sites/default/files/documents/library/cop12_res05_new_strp_e_0.pdf) 18 members, appointed in their own right for their wetland-relevant expertise. A large number of other bodies are invited to participate as observer organizations (Resolution XII.5 Annex 2). Over the past 20 years, the STRP has prepared a substantial body of guidance to support implementation of different aspects of the Convention (see “Convention implementation guidance” below). For further information about the STRP’s work, visit its web platform on http://strp.ramsar.org/.

The CEPA (Communication, Education, Participation and Awareness) Oversight Panel, established in 2005, oversees and provides advice on the implementation of the Convention’s CEPA Programme for 2016–2024, Resolution XII.9 http://www.ramsar.org/sites/default/files/documents/library/cop12_res09_cepa_e_0.pdf.

The Ramsar secretariat, hosted by IUCN in Gland, Switzerland, is the administrative body of the Convention, with responsibilities including providing advice and support to contracting parties and organizing, and preparing documentation for, official Convention meetings. The secretariat is now notable among global MEAs in being directed solely by its contracting parties and not by a United Nations body or agency.

At national level, within each contracting party, the government appoints a Ramsar “administrative authority” which has responsibility for within-country and international cooperation implementation of the Convention. The administrative authority is expected to appoint an STRP National Focal Point and two CEPA National Focal Points (one governmental and one nongovernmental), to designate Ramsar sites, and to establish a National Ramsar (or wetlands) Committee to provide national coordination and implementation advice.

Growth and Evolution of the Convention

Since its establishment in 1971, the Convention has progressively grown and now (as at February 2014) has 168 contracting parties (Fig. 1). Each contracting party commits to the designation and management of a coherent and comprehensive national network of Wetlands of International Importance (Ramsar sites) – wetlands which qualify under one or more of nine designation criteria (see Ramsar Convention Secretariat 2010). The global network of Ramsar sites is (as at September 2016) 2,242 sites covering over 2.15 million km^2 of wetlands and associated habitats, with new site designations being made at twice the rate during the past 10 years as previously (Fig. 1). Information on all Ramsar sites is publicly available through the Ramsar Sites Information Service (RSIS) on http://ramsar.wetlands.org/. A major redevelopment of the RSIS, designed to handle data from the revised format of the Information Sheet on Ramsar Wetlands (RIS) adopted by COP11 (see Table 2), was launched in 2015.

A Convention budget (funded by annual contributions from contracting parties) and secretariat (then called the bureau – services previously provided by IUCN and the International Waterfowl and Wetlands Research Bureau (IWRB)) were not established until 1987, at COP3. Although both the budget and secretariat staffing

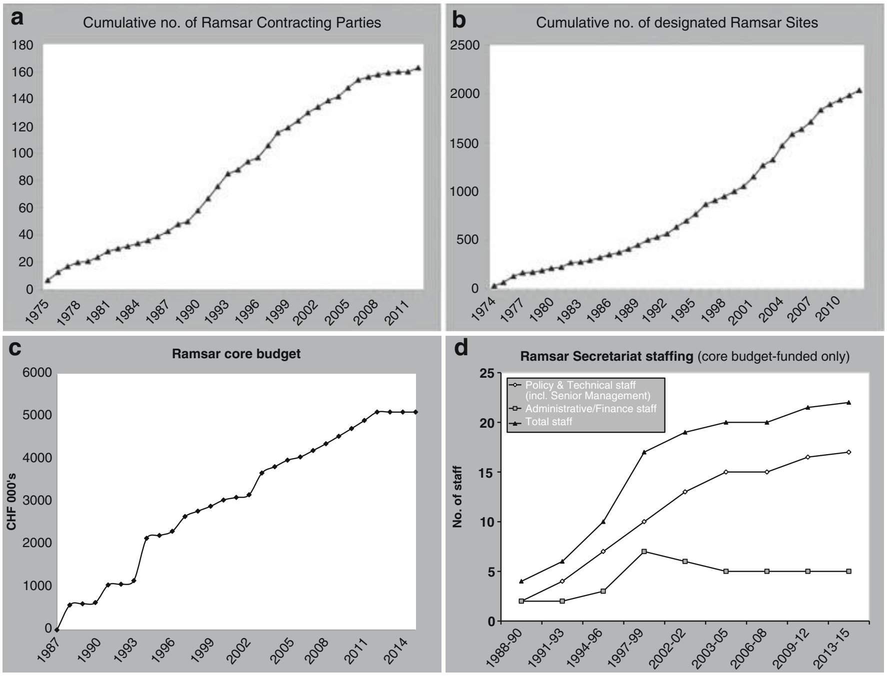

Fig. 1 Growth of the Ramsar Convention since its establishment in 1971: (**a**) number of contracting parties, (**b**) number of designated Wetlands of International Importance (Ramsar sites), (**c**) budget, and (**d**) secretariat staffing

have grown progressively since then, neither budget nor secretariat capacity has kept pace with Convention growth, and the budget has been flat lined (in absolute terms) since 2012 (Fig. 1).

In its early days, the Convention focused attention on the designation of Ramsar sites, particularly for waterbird populations. Since then the Convention has steadily evolved and developed to address its full originally intended scope: essentially all issues of wetlands and people, water, and ecosystems. In so doing, the Convention has recognized that delivering wise use depends on many cross-sectoral collaborations and partnerships and addressing social and cultural, as well as ecological, dimensions of wise use: many of the more recent decisions and guidance adopted by parties concern these approaches (see Tables 1 and 2). In particular the suite of wetlands and water-related guidance (Ramsar Handbooks 8–12) is the only such guidance on managing ecosystems for water and water for ecosystems adopted by governments for global implementation.

The Ramsar Convention has been at the forefront of developing and implementing practical synergies and collaborations between biodiversity-related Conventions and since 1996 has been recognized as the Convention on Biological Diversity's (CBD) lead implementation partner for wetlands. Collaboration is effected the Joint Work Plan (currently the fourth Joint Work Plan, for

[a]This revised RIS format, and its supporting strategic framework and guidelines, formally came into force on 1 January 2015

2011–2020). Thus, implementation of the commitments under the Ramsar Convention is simultaneously implementation of CBD commitments across the range of its thematic and cross-cutting programs of work, including the ecosystem approach, for wetlands. For further description of the progress and challenges of such MEA synergies, see Davidson and Coates (2011).

Convention Implementation Guidance

To support and guide governments and others in Convention implementation, since the early 1990s the Convention has progressively adopted a large suite of "wise use guidelines," most prepared through the work of the Convention's STRP. All such guidance is published thematically in the 20 volumes of the Ramsar Wise Use Handbooks, the most recent being the fourth edition, which includes all guidance adopted up to and including Ramsar's tenth Conference of Contracting Parties in 2008 (Table 1). Further, and revised, guidance was adopted by COP11 in 2012 (Table 2) and is available on http://www.ramsar.org/search?f[0]=type%3Adocument&f[1]=field_tag_body_event%3A366&f[2]=field_tag_body_event%3A415&f[3]=field_document_type%3A530&search_api_views_fulltext=.

Ramsar Convention: Ramsar Site Designation Process

52

David A. Stroud

Contents

Abstract

The designation of Wetlands of International Importance is one of the three "pillars" of the Convention on Wetlands of International Importance (Ramsar Convention). A primary motivation for the establishment of the Convention in the 1970s was the progressive loss of wetlands and negative consequences for biodiversity. One means of addressing this was to establish a mechanism by which states could commit to protect the most important wetlands in their territory (complemented by the wise use of all other wetlands). With sites designated under the World Heritage Convention, it is one of only two legal mechanisms for the global recognition of sites of international importance for biodiversity.

Introduction

The designation of international importance is one of the three "pillars" of the Convention on Wetlands of International Importance (Ramsar Convention). A primary motivation for the establishment of the Convention in the 1970s was the progressive loss of wetlands and negative consequences for biodiversity (Ramsar Convention 1971; Matthews 1993). One means of addressing this was to establish a mechanism by which states could commit to protect the most important wetlands in their territory (complemented by the wise use of all other wetlands). With sites designated under the World Heritage Convention, it is one of only two legal mechanisms for the global recognition of sites of international importance for biodiversity (de Klemm and Shine 1993).

The network extent grows with each designation. Updated statistics are available on the Convention's home page (www.ramsar.org). As at 18 July 2016, there were 2,241 listed Ramsar Sites covering an area of 2,152,476 km^2, slightly greater than the extent of Saudi Arabia (the 12th largest country in the world).

Development of a Global Network of Ramsar Sites: Vision and Objectives

Initially, the strategic direction given to the development of the List of Wetlands of International Importance (or Ramsar Sites) was limited, beyond an obligation to designate a single Ramsar Site as one of the legal requirements of Convention accession (Article 2).

The sixth meeting of the Conference of the Contracting Parties (COP 6), however, urged Parties through the Convention's Strategic Plan 1997–2002 (Ramsar Convention 1996b) to "increase the area of wetland designated for the List of Wetlands of International Importance particularly for wetland types that are under-represented either at the global or national levels."

At the time of COP 7 in 1999, as the number of Ramsar Sites was approaching 1,000, the Convention first adopted the *Strategic Framework and guidelines for the future development of the List of Wetlands of International Importance* (Ramsar Convention 1999) and has amended and added to it regularly since then, most substantially at COP 11 (Ramsar Convention 2012b). Its purpose is to provide a clearer view, or vision, of the long-term outcomes which the Convention is seeking to achieve through the Ramsar List. Advice is also offered to assist Contracting Parties (CPs) take a systematic approach to identifying priorities for future designations, in order to create national networks of Ramsar Sites which, when considered at the global level, fulfill the vision for the Ramsar List, which is:

> To develop and maintain an international network of wetlands which are important for the conservation of global biological diversity and for sustaining human life through the maintenance

of their ecosystem components, processes and benefits/services. (In this context, the Convention defined “ecosystem benefits” in accordance with the Millennium Ecosystem Assessment definition of ecosystem services as “the benefits that people receive from ecosystems.”)

Such an international network of wetland sites has to be built from coherent and comprehensive national networks of Ramsar Sites. The extent to which this has been achieved is highly variable. Several countries have a large area (Bolivia, Canada, Chad, Congo, and Russian Federation all with >10,000,000 ha) and/or numbers of sites (UK [170] and Mexico [142]), others few (26 Contracting Parties just have a single Ramsar Site as at 22 September 2012).

The distribution of sites globally is highly uneven, with most designations having been made in Europe (Figs. 1 and 2) and fewest in Oceania. To a significant extent, this reflects patterns of accessions to the Convention – the earliest Contracting

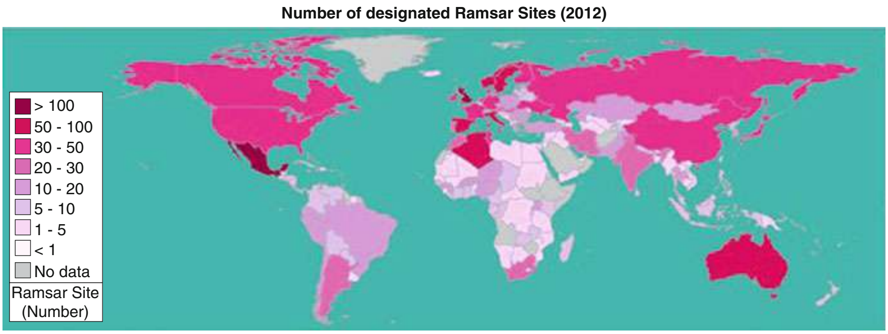

Fig. 1 Distribution of numbers of Ramsar Sites by Contracting Party as at 5 November 2012 (Data from www.ramsar.wetlands.org)

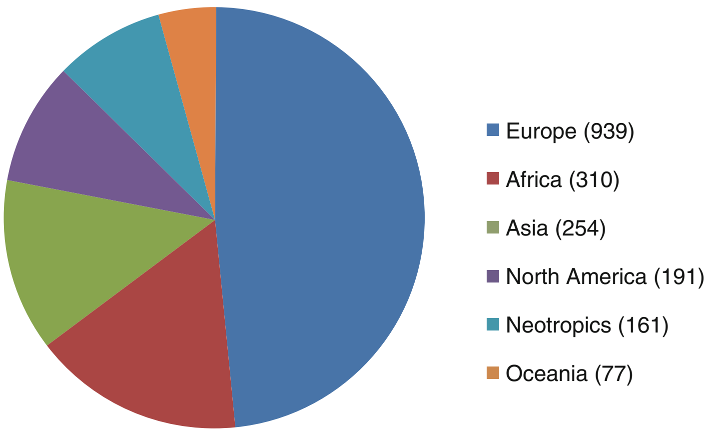

Fig. 2 Number of Ramsar Sites by region; data as at November 2011 (Data from www.ramsar.wetlands.org)

Parties joining the Convention were largely from Europe, with most recent accessions being from Oceania.

The Convention established (Ramsar Convention 2012b) the following five objectives to realize the vision for the Ramsar List (not in priority order):

1. To establish national networks of Ramsar Sites in each Contracting Party which fully represent the diversity of wetlands and their key ecological and hydrological functions;
2. To contribute to maintaining global biological diversity through the designation and management of appropriate wetland sites;
3. To foster cooperation among Contracting Parties, the Convention's International Organization Partners, and local stakeholders in the selection, designation, and management of Ramsar Sites;
4. To use the Ramsar Site network as a tool to promote national, supranational/regional, and international cooperation in relation to complementary environment treaties; and
5. To use national Ramsar Site networks to provide essential ecosystem services/ benefits, especially related to water, that contribute to human health, livelihoods, and well-being.

Designation and Listing

The designation of (at least one) wetland of international importance is one of the central obligations of CPs. Designation of "at least one wetland" (Article 2.4) is part of the accession process when states join the Convention. Thereafter, "each Contracting Party shall designate suitable wetlands within its territory for inclusion in the List of Wetlands of International Importance" (Article 2.1). It is this requirement to designate geographical territory on accession which constrains non-state parties (such as Regional Economic Integration Organisations for example the European Union) from becoming signatories to the Convention.

The process of "designation" of a Ramsar Site by the state party – in which it assumes legal responsibility for the wise use of the site – is a process distinct from the addition of that site to the Convention's List of Wetlands of International Importance. That formal "listing" by the Secretariat requires acceptance of a sufficient quality map and a supporting information sheet (RIS) submitted by the Contracting Party (see Sect. 9 of Ramsar Convention 2012b).

Typically, designation and listing occur together, but there are some sites designated by Parties which remain to be listed.

Ramsar Site Identification and Criteria

Throughout its evolution, the Convention has developed criteria for the designation of Ramsar Sites which have been kept under constant review (Matthews 1993; Stroud 2013). It has supplemented these with regularly updated guidelines to assist

Contracting Parties (CPs) in their interpretation and application of the criteria reflecting the development of conservation science (Ramsar Convention 2012b).

Essentially, wetlands may be defined as of international importance because they hold representative, rare, or unique wetland types (Criterion 1), rare ecological communities or species including at critical life cycle stages (Criteria 2–4), or important numbers of birds (Criteria 5 and 6), fish (Criteria 7 and 8), or other animal taxa (Criterion 9) (Box 1).

Ramsar Site Description

The organization and reporting of information about Ramsar Sites lie at the heart of the Convention's activities. This key need was specifically highlighted in the Final Act of the 1971 Conference in Ramsar, Iran, which stated that "the entries in the List of Wetlands of International Importance which is to be maintained under the Convention could usefully be supplemented by descriptions of the biotopes involved and an enumeration of the bird species especially in need of protection therein." (Carp 1972). The emphasis given to this information requirement at that time, before any consideration had been given to other processes supporting the Convention, was significant. It was not until COP 4, however, that a RIS was formally established as a means of collating this information (Ramsar Convention 1990), and its format has been progressively revised at subsequent COPs at a frequency that balanced the need for stability in established processes with both the development of the Convention's growing needs for better strategic overviews of the List of Ramsar Sites and the technological abilities to disseminate this key information to the wide spectrum of users.

The RIS is used to describe the site at the time of designation in sufficient detail to provide a baseline for subsequent monitoring to detect any changes to these ecological and hydrological attributes. Parties are requested to update the information in the RIS, either when there is an actual or potential change in ecological character or at periods not longer than 6 years (Ramsar Convention 1996a).

In 2012, COP 11 agreed a major restructuring of the format of the RIS and a move to develop systems that will allow for its electronic submission (Ramsar Convention 2012a). Aspects of the 2012 RIS format such as its clearer focus on species information, and – for the first time – the collection of simple information on ecosystem services provided by sites, have been acknowledged as potentially revolutionizing our understanding of both individual Ramsar Sites and the global network.

Obligations Following from Ramsar Designation

The act of designating (listing) a wetland as internationally important under the Convention is a first step along a conservation and sustainable use pathway, the endpoint of which is achieving the long-term wise (sustainable) use of the site.

Article 3.2 of the Convention determines that "each Contracting Party shall arrange to be informed at the earliest possible time if the ecological character of any wetland in its territory and included in the List has changed, is changing or is likely to change." Accordingly, the Ramsar Convention has developed the concept of "ecological character" for wetlands, which is defined (Ramsar Convention 2005a) as:

> Ecological character is the combination of the ecosystem components, processes and benefits/services that characterise the wetland at a given point in time.

Parties are expected to manage their Ramsar Sites in such a way as to maintain the ecological character of each site and, in so doing, retain those essential ecological and hydrological functions which ultimately provide its ecosystem services. Ecological character is therefore an indication of the "health" of the wetland, and changes to ecological character outside its natural range of variation may signal that uses of a site, or externally derived impacts on the site, are unsustainable and may lead to the degradation of natural processes and thus the ultimate breakdown of the ecological, biological, and hydrological functioning of the wetland.

Delisting

Guidance on the issue of the removal of a Ramsar Site from the international list has been provided by the COP as related to several scenarios.

The first relates to the provisions established under Article 2.5 which allow a party "...because of its urgent national interests, to delete or restrict the boundaries of wetlands already included by it in the List...." Typically, such provisions have been exercised where development or other activities in the national interest unavoidably conflict with the status of a Ramsar Site. Where such deletion or boundary restriction occurs, Article 4.2 requires that the Contracting Party "...should as far as possible compensate for any loss of wetland resources." Resolution VIII.20 (Ramsar Convention 2002a) gave general guidance for interpreting "urgent national interests" under Article 2.5 of the Convention and in considering compensation under Article 4.2.

Resolution VIII.22 (Ramsar Convention 2002b), however, recognized situations other than Article 2.5 provisions in which Ramsar Site boundaries may need refinement notably where:

(a) A Ramsar Site never met the criteria for designation
(b) Part or all of a Ramsar Site unavoidably loses the values, functions, and attributes for which it was included or was designated in error
(c) A Ramsar Site at the time of listing met the criteria, but, while its interests remain unchanged, it later fails to meet the criteria because of a change in those criteria or in the population estimates or parameters which underpin them

Resolution IX.6 (Ramsar Convention 2005b) provided guidance on principles and procedures for situations not foreseen in the Convention text concerning the loss or deterioration of the ecological character of listed wetlands under circumstances other than those addressed by Article 2.5.

Different National Implementation Concepts

One of the strengths of the Convention is its flexibility to a wide range of differing national circumstances – particularly manifest in the range of different models of national implementation of the Ramsar Site concept. At one extreme, some countries, for example, UK, tightly define boundaries of sites which are given a high level of protection (albeit for multifunctional uses) under national legislation and where legal protection regimes are established prior to the designation.

A contrasting approach, equally valid under the Convention, uses the designation to give status to landscape or catchment scale wetlands which may have no prior national legislative protection. In these cases, the Ramsar status is used to help resolve conservation or land-use issues as they arise. Such wide-scale Ramsar Sites may also contain other, more restricted protected sites with a higher level of national protection. For example, France has designated a number of large-scale Ramsar Sites containing more strictly protected and discrete Natura 2000 sites.

Sources of Further Information

A wealth of information on Ramsar Sites and their designation is available on the Convention's website. Considerable background information is given by Ramsar Convention Secretariat 2010 and Ramsar Convention 2012b. The Ramsar Sites Information Service (www.ramsar.wetlands.org) is the formal database of information on Ramsar Sites maintained by Wetlands International on behalf of the Convention and gives access to detailed information on listed sites and a wide range of summary statistics.

Ramsar Convention: Transboundary Ramsar Sites

53

Royal C. Gardner

Contents

Abstract

A transboundary Ramsar Site refers to "an ecologically coherent wetland [that] extends across national borders" when "the Ramsar Site authorities on both or all sides of the border have formally agreed to collaborate in its management, and have notified the [Ramsar] Secretariat of this intent." Such a cooperative management arrangement is one way that contracting parties to the Ramsar Convention may implement their duty of international cooperation, including the responsibilities related to Article 5 of the Convention, which requires contracting parties to consult with one another in the case of shared wetlands or water systems. A site's designation as a transboundary Ramsar Site acknowledges the existence of a cooperative management arrangement, but it is not a distinct legal status for the Ramsar Sites involved. Accordingly, such a designation does not create additional international legal obligations beyond those already imposed by the Ramsar Convention.

Introduction

A transboundary Ramsar Site refers to "an ecologically coherent wetland [that] extends across national borders" when "the Ramsar Site authorities on both or all sides of the border have formally agreed to collaborate in its management, and have notified the [Ramsar] Secretariat of this intent" (Ramsar Convention Secretariat 2006). Such a cooperative management arrangement is one way that Contracting Parties to the Ramsar Convention may implement their duty of international cooperation, including the responsibilities related to Article 5 of the Convention which requires Contracting Parties to consult with one another in the case of shared wetlands or water systems. A site's designation as a transboundary Ramsar Site acknowledges the existence of a cooperative management arrangement, but it is not a distinct legal status for the Ramsar Sites involved. Accordingly, such a designation does not create additional international legal obligations beyond those already imposed by the Ramsar Convention.

Transboundary Ramsar Sites

The first formal transboundary Ramsar Site occurred when Hungary and Slovakia notified the Ramsar Secretariat in 2001 of their intention to manage Hungary's Baradla cave system and its related wetlands and Slovakia's Domica in a cooperative manner. The Contracting Parties have flexibility in how to manage such sites; there is no prescribed management approach. As Table 1 indicates, as of September 2016 there were 18 formal transboundary Ramsar Sites. All these transboundary Ramsar Sites are located in Europe, except for Niumi-Saloum, which extends across the borders of Gambia and Senegal. The Ramsar Secretariat maintains a current list of transboundary Ramsar Sites on its website.

54 Ecological Character Concept of the Ramsar Convention

Dave Pritchard

Contents

Abstract

The Ramsar Convention requires every Contracting Party to arrange to be informed about change or potential change in the ecological character of its listed Ramsar Sites. Definitions of "ecological character" and "change" were agreed in 1996, then revised in 1999 and 2005. These definitions emphasise the interrelationships between all the processes and attributes that characterise a given wetland, and the latest version includes ecosystem services provided by the wetland as part of the character. Maintenance of ecological character is now the conceptual basis for obligations under the Convention applying to all wetlands, whether listed or not; and extensive guidance and commentaries have been published to support implementation of this.

Introduction

The Ramsar Convention text, as adopted in 1971 (Matthews 1993), introduced the concept of the "ecological character" of wetlands in its Article 3.2, which required every Contracting Party government to "...arrange to be informed at the earliest possible time if the ecological character of any wetland in its territory and included in the List has changed, is changing or is likely to change as the result of technological developments, pollution or other human interference." ("The List" refers to the List of Wetlands of International Importance, usually known as Ramsar sites, created under the Convention.)

Measures to implement this requirement were elaborated by several of the early meetings of the Conference of Parties (COP), but it was not until the sixth meeting, in 1996, that "ecological character" was formally defined for the first time (it has been amended twice since then). COP6 Resolution VI.1 gave a "working definition, to be assessed further," as follows: "The 'ecological character' is the structure and inter-relationships between the biological, chemical, and physical components of the wetland. These derive from the interactions of individual processes, functions, attributes and values of the ecosystem(s)" (Ramsar Convention 1996).

"Change in ecological character" of a wetland was defined at the same time (again provisionally) as "the impairment or imbalance in any of those processes and functions which maintain the wetland and its products, attributes and values."

The Resolution and its annex added an explanation of how these definitions were to be interpreted. First, it emphasized that the working definitions were "relevant to the management of wetlands in general" (i.e., not only to Ramsar sites). It further noted that "change in the ecological character of a site is interpreted as meaning adverse change, in line with the context of Article 3.2 of the Convention [...]. The definition refers explicitly to adverse change caused by human activities. It excludes the process of natural evolutionary change occurring in wetlands. It is also recognised that wetland restoration and/or rehabilitation programmes may lead to favourable human-induced changes in ecological character."

Key terms used in the definitions ("processes," "functions," "values," "products," and "attributes") were themselves defined in the same decision, but in ways which have since been superseded by the definitions quoted below. The annex to the Resolution also provided "guidelines for describing and maintaining ecological character of listed sites."

Reworking of the Concept

Following deliberations by the Ramsar Scientific and Technical Review Panel (STRP), a first reworking of the definitions was agreed by the Parties at COP7 in 1999 (Ramsar Convention 1999). Resolution VII.10 adopted the following: "ecological character is the sum of the biological, physical, and chemical components of the wetland ecosystem, and their interactions, which maintain the wetland and its products, functions, and attributes"; and "change in ecological character is the impairment or imbalance in any biological, physical, or chemical components of the wetland ecosystem, or in their interactions, which maintain the wetland and its products, functions and attributes."

The STRP was then asked by COP8 in 2002 to "further review and, as appropriate, develop guidance and report to COP9 concerning identified gaps and disharmonies in defining and reporting the ecological character of wetlands, including, inter alia, harmonisation of definitions and terms in the guidance on inventory, assessment, monitoring and management of the ecological character of wetlands." Following this work, and in particular some conceptual alignment between the Convention and the Millennium Ecosystem Assessment (MA), COP9 in 2005 agreed the definitions that remain in use today (Resolution IX.1 Annex A: Ramsar Convention 2005).

In these, "**ecological character**" was defined as "**the combination of the ecosystem components, processes and benefits/services that characterise the wetland at a given point in time**." The definition is to be read with the accompanying notes which explain that "within this context, ecosystem benefits are defined in accordance with the MA definition of ecosystem services as 'the benefits that people receive from ecosystems'"; and "the phrase 'at a given point in time' refers to Resolution VI.1 paragraph 2.1, which states that 'it is essential that the ecological character of a site be described by the Contracting Party concerned at the time of designation for the Ramsar List, by completion of the Information Sheet on Ramsar Wetlands (as adopted by Recommendation IV.7)'."

"**Change in ecological character**" was defined as follows: "**For the purposes of implementation of Article 3.2, change in ecological character is the human-induced adverse alteration of any ecosystem component, process, and/or ecosystem benefit/service.**" The accompanying notes explain that "the inclusion of specific reference to Article 3.2 of the Convention text within the definition is designed to clarify the maintenance obligation for the ecological character of listed Wetlands of International Importance (Ramsar sites) under Article 3.2, and to note that such change concerns only adverse change caused by the actions of people. [. . .] For the purposes under the Convention, this definition therefore excludes the processes of natural evolutionary change occurring in wetlands and also excludes positive human-induced change. However, it should be noted that other actions adopted by the Convention, such as those concerning assessing the overall status and trends of wetlands and Ramsar sites, require information on all types of change in ecological character – positive and negative, natural and human-induced".

Technical Guidance

Subsequently, extensive guidance has been adopted on the operation of these concepts (Ramsar Convention Secretariat 2013). This includes guidance on the systematic description of the ecological character of individual wetlands as a baseline against which to assess change (annex to Resolution X.15) (Ramsar Convention 2008). This highlights, among other things, the fact that the concept of ecological character covers more than merely a list of the ecosystem's components, processes, and services, requiring also attention to the additional idea of what they represent *in combination*, since it is "a holistic rather than a reductionist concept." The annex to Resolution X.16 provides a "Framework for processes of detecting, reporting and responding to change in wetland ecological character," and further detail on these aspects is set out in a background paper (DOC.27) provided to COP10 in 2008 and in volume 19 of the *Ramsar Wise Use Handbooks* (4th edition, 2010).

Wise Use Concept of the Ramsar Convention

55

Dave Pritchard

Contents

Abstract

The term "wise use", as it relates to wetlands, originates in the text of the Ramsar Convention adopted in 1971. Initially the term was not defined; but early discussions made clear that it expressed an aim to combine conservation and sustainable use of resources, making Ramsar the first Convention to embrace what later became the widely accepted concept of "sustainable development". A first formal definition of "wise use" was adopted in 1987 by the Convention's Parties, who then modified it in 2005. This later definition emphasises "maintenance of wetland ecological character" as the central tenet of the concept. A quantity of guidance material has been published to support the implementation of wise use for all wetlands.

Introduction

The term "wise use," as it relates to wetlands, originates in the text of the Ramsar Convention adopted in 1971. Article 3.1 of the Convention requires Contracting Party governments to "... formulate and implement their planning so as to promote ... as far as possible the wise use of wetlands in their territory." It is thus an obligation that must be implemented through national-level measures; and it applies to all wetlands, whether specially protected or not.

Subsequent definitions and commentaries have concentrated on this provision for wise use of wetland ecosystems, largely ignoring the fact that the Convention also applies it to species populations ("wise use of migratory stocks of waterfowl," Article 2.6).

Developing the Concept of Wise Use

Initially the term was not defined; but early discussions made clear that it was intended to cover maintenance of the "ecological character" of wetlands, as a basis not only for nature conservation but also for sustainable development (Davis 1992). This made Ramsar the first Convention to seek to combine conservation and sustainable use of resources.

This thinking eventually became reflected in the first formal definition of wise use of wetlands adopted by the Conference of Parties at their third meeting (COP3) in 1987 (Davis 1993), when it was defined as "their sustainable utilization for the benefit of humankind in a way compatible with the maintenance of the natural properties of the ecosystem."

"Sustainable utilization" was defined at the same time as "human use of a wetland so that it may yield the greatest continuous benefit to present generations while maintaining its potential to meet the needs and aspirations of future generations." This echoed the definition of "sustainable development" put forward in the same year by the UN World Commission on Environment and Development (Brundtland Commission) as "development that meets the needs of the present without compromising the ability of future generations to meet their own needs."

Mission statements adopted by the Ramsar Convention have reinforced this connection, by emphasizing that conservation and wise use of all wetlands under the Convention is intended to be "a contribution towards achieving sustainable development throughout the world."

These definitions all tread delicately around the accommodation of both "constant state" and "progressive development" ideas of "use."

The terminology continued to evolve thereafter, in contexts such as the 1992 Convention on Biological Diversity's approach to "sustainable use" and the development of the concept of "ecosystem services" by the Millennium Ecosystem Assessment, completed in 2005. Ramsar Parties asked the Convention's Scientific and Technical Review Panel to "review the wise use concept, its applicability, and its consistency with the objectives of sustainable development" in light of these developments.

Based on the Panel's findings, COP9 in 2005 adopted Resolution IX.1, Annex A of which included an updated definition of wise use (Ramsar Convention 2005; Finlayson et al. 2011), as follows: "Wise use of wetlands is the maintenance of their ecological character, achieved through the implementation of ecosystem approaches, within the context of sustainable development."

The first clarifies that "ecosystem approaches" include, among others, those elaborated by the Convention on Biological Diversity and by the Helsinki and OSPAR Commissions. This highlights factors such as integrated management, stakeholders' participation in decision-making, transparency about trade-offs, and equitability of outcomes. Mechanisms applied under Ramsar such as Integrated River Basin Management, Integrated Water Resources Management, Integrated Coastal Zone Management, and Integrated Marine and Coastal Area Management had, in effect, already been exemplifying this approach. (Indeed, wise use is regarded as the longest-established example among intergovernmental processes of the implementation of an ecosystem-based approach to the conservation and sustainable development of natural resources.)

The second footnote explains that the phrase "in the context of sustainable development" is intended to recognize that "whilst some wetland development is inevitable and that many developments have important benefits to society, developments can be facilitated in sustainable ways by approaches elaborated under the Convention, and it is not appropriate to imply that 'development' is an objective for every wetland."

The successive definitions of "wise use" have brought it to equate both to "sustainable use" and to the "maintenance of the ecological character" of all wetlands (Finlayson et al. 2011). That latter phrase originated with the Convention's provisions for conservation of special sites, but since it in turn has been redefined in a way that now incorporates "ecosystem services" in the sense of the Millennium Ecosystem Assessment, a fusion of two historically distinct ideas has been achieved. While "services" had previously been seen as *flowing from* "character," they are now seen as an integral part of it. While "use" and "conservation" had previously been seen as different things, to be reconciled by a "balancing" notion of sustainability, wise use is now primarily about *maintaining the capability for use*, rather than *using, subject to a sustainability caveat*.

COP4 in 1990 adopted initial guidelines for the implementation of wise use, followed by the adoption of additional guidance at COP5 in 1993 (Ramsar Convention 1990, 1993). These were groundbreaking in their time, but have since largely been superseded by an increasingly comprehensive suite of other guidance on specific aspects of Ramsar implementation. Nonetheless, the landmark adoption of a "conceptual framework for the wise use of wetlands and the maintenance of their ecological character" in 1990 and the production of successive editions of 21 volumes of the Convention's "toolkit" of "Handbooks for the wise use of wetlands" testify to the continuing centrality of this concept in global wetland conservation (Ramsar Convention Secretariat 2010).

Convention of Migratory Species (CMS) and Wetland Management

56

Robert J. McInnes and Nick C. Davidson

Contents

Abstract

Migratory species, including waterbirds, cetaceans and turtles, face many challenges as they cross national borders. The Convention on the Conservation of Migratory Species of Wild Animals – *or as it is more commonly referred to as the Convention on Migratory Species* (*CMS*) *or the Bonn Convention* – is an environmental treaty that provides a global platform for the conservation and sustainable use of migratory animals and their habitats. The Convention was signed in 1979 entered into force in 1983. Since this date, the Convention's membership has grown steadily, and in 2015 it includes over 100 parties from Africa, Central and South America, Asia, Europe, and Oceania. CMS is the only global convention specializing in the conservation of migratory species, their habitats, and migration routes.

https://doi.org/10.1007/978-90-481-9659-3_111

Origins of the Convention

Migratory species, including waterbirds, cetaceans and turtles, face many challenges as they cross national borders (Kirby et al. 2008). The Convention on the Conservation of Migratory Species of Wild Animals – *or as it is more commonly referred to as the Convention on Migratory Species* (*CMS*) *or the Bonn Convention* (http://www.cms.int/) – is an environmental treaty that provides a global platform for the conservation and sustainable use of migratory animals and their habitats. The Convention was signed in 1979 in Bad Godesberg, a suburb of Bonn (hence the name), and entered into force in 1983 (Lyster 1989). Since this date, the Convention's membership has grown steadily, and in 2015 it includes over 100 parties from Africa, Central and South America, Asia, Europe, and Oceania. CMS is the only global convention specializing in the conservation of migratory species, their habitats, and migration routes. However, CMS complements and cooperates with a number of other international organizations, including the Ramsar Convention, nongovernmental organizations, and the private sector.

CMS brings together the States through which migratory animals pass (termed "range states") and establishes the legal foundation for internationally coordinated conservation measures throughout a migratory range. The CMS mandate covers all taxa of species which are regarded as migratory, under a geopolitical definition of "migratory" of species which cross national boundaries on a regular and predictable basis: "Migratory species" means the entire population or any geographically separate part of the population of any species or lower taxon of wild animals, a significant proportion of whose members cyclically and predictably cross one or more national jurisdictional boundaries" (CMS text Article 1.1 a).

Migratory species threatened with extinction are listed on Appendix I of the Convention. CMS parties work closely toward strictly protecting these animals; managing, conserving, or restoring the habitats where they live; understanding and working to remove obstacles to migration; and controlling other factors that might endanger them. Besides establishing obligations for each State joining the Convention, CMS promotes concerted action among the range states of many of these species. CMS and its daughter agreements determine policy and provide further guidance on specific issues, such as avian influenza or minimizing the risk of poisoning to migratory birds, through various strategic plans, action plans, resolutions, decisions, and guidelines.

International Cooperation and Protection

Many migratory species depend on trans-boundary cooperation for their protection. The migratory species that require or would significantly benefit from international cooperation are listed in Appendix II of the Convention. In order to successfully manage wetlands that are utilized by trans-boundary migratory species, the Convention encourages the range states to conclude global or regional agreements. In this respect, CMS acts as a framework Convention. The agreements may range from legally binding treaties (called agreements) to less formal instruments, such as memoranda of understanding, and can be adapted to the requirements of particular regions. Consequently, CMS influences the management and wise use of migratory wetland-dependent species of fish, birds, and mammals through a number of these established agreements and memoranda of understanding. These include:

Agreements
- Wadden Sea Seal Agreement
- Agreement on the Conservation of Cetaceans in the Black Sea, Mediterranean Sea, and Contiguous Atlantic Area (ACCOBAMS)
- Agreement on the Conservation of Small Cetaceans in the Baltic, North East Atlantic, Irish and North Seas (ASCOBANS)
- African-Eurasian Migratory Waterbird Agreement (AEWA)
- Agreement on the Conservation of Albatrosses and Petrels (ACAP)
- Agreement on the Conservation of Gorillas and Their Habitats

Memoranda of Understanding
- Conservation Measures for the Aquatic Warbler (*Acrocephalus paludicola*)
- Conservation Measures for the Siberian Crane
- Conservation and Management of Marine Turtles and Their Habitats of the Indian Ocean and South-East Asia (IOSEA)
- Conservation Measures for Marine Turtles of the Atlantic Coast of Africa
- Conservation of High Andean Flamingos and Their Habitats
- Conservation Measures for the Eastern Atlantic Populations of the Mediterranean Monk Seal (*Monachus monachus*)
- Conservation of Cetaceans and Their Habitats in the Pacific Islands Region
- Conservation Measures for the Slender-Billed Curlew
- Conservation of the Manatee and Small Cetaceans of Western Africa and Macaronesia
- Conservation Measures for the Ruddy-Headed Goose (*Chloephaga rubidiceps*) (between the Argentine Republic and the Republic of Chile)
- Conservation of Migratory Sharks
- Conservation Measures for the West African Populations of the African Elephant (*Loxodonta africana*)

Further information on each of these agreements and memoranda of understanding can be found on the CMS Family Portal on: http://www.migratoryspecies.org/.

One of the most well-established examples of cooperation through an agreement is the Agreement on the Conservation of African-Eurasian Migratory Waterbirds (AEWA) (http://www.unep-aewa.org/). Developed under the framework of CMS, and administered by the United Nations Environment Programme (UNEP), AEWA brings together countries and the wider international conservation community, including the Ramsar Convention, in an effort to establish coordinated conservation and management of migratory waterbirds throughout their entire migratory range (Boere and Lenten 1998). Covering migratory waterbirds and their wetland habitats across Africa, Europe, the Middle East, Central Asia, Greenland, and the Canadian Archipelago, all the species covered by AEWA are "wetland dependent" and so are also covered by the provisions of the Ramsar Convention, and Ramsar's established mechanisms such as for international waterbird flyway cooperation, and the designation and management of Ramsar Sites for waterbirds.

The high relevance of the Ramsar Convention mechanisms to AEWA and the need for collaborative implementation of the two instruments were most recently recognized by the 5th Meeting of Parties to AEWA through its adoption of two decisions (AEWA 2012a, b).

Future Challenges

Migratory wetland-dependent species are a major component of faunal biodiversity. Not only do these species represent a significant proportion of the world's genetic variety, they also play an essential role in ecosystem functioning and dynamics through, for instance, the pollination of plants or the dispersal of seeds.

In its new strategic plan for migratory species (CMS 2014), the Convention identified a range of issues and future challenges for the conservation of migratory species, as follows.

Migratory species have their own special vulnerabilities. Migratory journeys expose them to heightened survival risks, and habitat requirements are often a complex mix of different components in breeding areas, nonbreeding areas, and the places in between. Concentrations of large numbers of individuals during specific periods at specific sites also increase the risk of serious impacts from negative pressures at those sites.

Barriers to migration pose special challenges, whether or not in the form of physical obstacles, which may cause direct mortality, or fragmentation of ecological resources disrupting movement from one place to another.

Conservation strategies therefore need to give holistic attention not only to populations, species, and habitats, but to the entire span of migratory routes and the functioning of the migration process. Many of the actions defined in this plan are accordingly directed toward "migratory systems," a concept which reflects the interdependent complexes of places, routes between places, populations, ecological factors, and temporal cycles involved.

The repeating cycles and trans-boundary ranges inherent to the phenomenon of migration are fundamental to the ability of the planet to support humankind and biodiversity overall. Migration is a key adaptation to natural rhythms and evolutionary changes; and by the same token both migratory species and their habitats can be affected/disrupted by human impacts, including climate change.

A great many migratory species are of major direct and indirect importance for people's food security and livelihoods. Many human communities rely on the regular influx of migratory animals: as a basis for subsistence; for economically and/or culturally important hunting, fishing, tourism, and recreation; or to maintain ecosystem function in a way that allows another resource to be harvested. Levels of use by one community can significantly affect the availability of the resource to communities in different, possibly distant, locations.

The conservation and sustainable use of migratory species is therefore a key contribution to wider aims of sustainable development and requires global attention.

57 Convention on Biological Diversity (CBD) and Wetland Management

David Coates

Contents

Abstract
The Convention on Biological Diversity (CBD) was inspired by the world's growing commitment to sustainable development. Its objectives are the conservation of biological diversity, the sustainable use of its components, and the fair and equitable sharing of benefits arising from the use of genetic resources. The CBD arose from the United Nations Conference on Environment and Development. The convention currently has 193 parties, and, excepting the United States, all parties of the Ramsar Convention are also parties to the CBD. This section outlines the approach to wetlands under the CBD, development of collaboration between the Ramsar Convention on Wetlands and the CBD, and constraints to, and opportunities for further, incorporation of wetlands management under the CBD.

Introduction

The Convention on Biological Diversity (CBD) was inspired by the world's growing commitment to sustainable development. Its objectives are the conservation of biological diversity, the sustainable use of its components, and the fair and equitable sharing of benefits arising from the use of genetic resources (www.cbd.int). The CBD arose from the United Nations Conference on Environment and Development (the Rio "Earth Summit," 1992). The convention currently has 193 parties, and, excepting the United States, all parties of the Ramsar Convention are also parties to the CBD. This section outlines the approach to wetlands under the CBD, development of collaboration between the Ramsar Convention on Wetlands and the CBD, and constraints to, and opportunities for further, incorporation of wetlands management under the CBD.

Wetlands Under the CBD and Collaboration with the Ramsar Convention

"Biodiversity," under the CBD, is defined as the variability among living organisms from all sources including, inter alia, terrestrial, marine, and other aquatic ecosystems and the ecological complexes of which they are part: this includes diversity within species, between species, and of ecosystems (Article 2 of the Convention – http://www.cbd.int/doc/legal/cbd-en.pdf). On this basis, any biodiversity living in or associated with wetlands as well as wetlands themselves (as ecosystems) are included under the scope of the CBD. In recent years, and in parallel with shifts in broader dialogues, including under the Ramsar Convention, consideration of "biodiversity" has moved beyond considering "species, genes, and ecosystems" to include a focus on the role of biodiversity in underpinning **ecosystem services** (benefits derived from ecosystems by people), thus assisting with improved articulation of the relationship between the objectives of the CBD and sustainable development.

The CBD has adopted the Ramsar Convention definition of "wetland" (decision VII/4 para. 27 http://www.cbd.int/decision/cop/?id=7741) which frames how wetlands are considered under its mandate. Collaborative work between Ramsar and the CBD is recognized as a model for how such streamlining can be done under existing multilateral environmental agreements (**MEAs**), while recognizing that each MEA has distinct but overlapping scope and mandate (for the most recent, see CBD COP10 decision X/20, http://www.cbd.int/decision/cop/?id=12286, and Ramsar COP-10 Resolution X.11, http://www.ramsar.org/pdf/res/key_res_x_11_e.pdf). As early as 1996, the Ramsar Convention was recognized as the "lead implementation partner" on wetlands for the CBD (Convention on Biological Diversity COP3 199, decision III/21). In essence, implementation of the commitments under the Ramsar Convention is simultaneously implementation of the CBD.

The history of collaboration between the two conventions, including implementation, is reviewed by Davidson and Coates (2011). In practice, Ramsar-CBD collaboration has been progressive and incremental, moving from affirmations of common interest, through recommending/adopting guidance prepared by one convention for use by the other, for example, CBD's impact assessment guidelines adopted by Ramsar with interpretation for their application in the Ramsar context (Ramsar COP-10 Resolution X.17 http://www.ramsar.org/pdf/res/key_res_x_17_e.pdf), to joint review and development of programs and guidance, including joint preparation and publication of technical reports requested by parties, and Ramsar's lead in undertaking the 2010 review and revision of the CBD program of work in the biological diversity of inland waters, providing the basis for the adoption of CBD COP10 Resolution X/28 on inland water biodiversity (http://www.cbd.int/decision/cop/?id=12294). The Ramsar guidance on wetland management, including relevant resolutions of the Ramsar Convention, supporting information, and in particular the *Ramsar Handbooks* for the wise use of wetlands (http://www.ramsar.org/cda/en/ramsar-pubs-handbooks/main/ramsar/1-30-33_4000_0__), is therefore de facto guidance for the CBD.

Following its inception, the development of policies and guidance under the CBD was dominated by the identification and adoption of various thematic programs of work and crosscutting issues as mechanisms to identify specific actions that need to be taken in order to fulfill the objectives of the convention (http://www.cbd.int/programmes/). The thematic programs of work are "biome" or sector based and include agricultural, dry and subhumid lands, forest, inland waters (which the Ramsar Convention was instrumental in designing), islands, marine, and coastal and mountain biodiversity. There is no specific program of work on "wetlands" which are covered most immediately by the programs of work on inland waters (where all identifiable habitats are wetlands using the Ramsar definition) and marine and coastal biodiversity (where most habitats up to 6 m depth are wetlands, using the Ramsar definition, which essentially excludes open oceans). There is however recognition that wetlands are ubiquitous and can be found in dry and subhumid areas, forests, agricultural areas, mountains, and islands and are therefore also relevant to these areas (decision VII/4, paragraph 11, http://www.cbd.int/decision/cop/?id=7741). Wetlands are pertinent to all of the CBD's crosscutting issues (which include topics such as climate change, gender, invasive alien species, etc.) among which **Wetlands of International Importance** (**Ramsar Sites**) are of particular relevance the CBD's crosscutting activities on protected areas.

The Strategic Plan for Biodiversity (2011–2020), and its **Aichi Biodiversity Targets**, has become the accepted framework for implementation for the MEAs, including for the CBD and the Ramsar Convention (see Biodiversity-Related Conventions and Ramsar). This has enabled improved opportunities for more holistic approaches to wetlands under the CBD, where the programs of work are seen as tools to support broader objectives. The improved recognition of water as an ecosystem service, and the role of wetlands, and other ecosystems, as natural infrastructure in supporting this service, significantly increases opportunities for recognizing the role of wetlands under the CBD and other MEAs.

Future Challenges

Despite significant areas of progress, there continue to be several constraints and limitations in addressing wetlands under the CBD as illustrated by the Ramsar-CBD cooperation achieved in practice (Davidson and Coates 2011). Most achievements have so far been at the global scale, through the work of the secretariats and the conventions' scientific and technical subsidiary advisory bodies (Ramsar's Scientific & Technical Review Panel (STRP) and CBD's Subsidiary Body on Scientific, Technical & Technological Advice (SBSTTA)). Although called for in both CBD and Ramsar decisions on collaboration between conventions, there is as yet much less consistency in the extent of national-scale communication and collaborative implementation including between the convention's respective national focal points, which in turn has been recognized as a key precondition to establish harmonized national reporting (UNEP-WCMC 2009).

Despite the early recognition of the importance of an ecosystem approach to implementation (CBD decision III/21, 1996), CBD parties and their decisions have focussed on wetlands mainly in the context of the CBD program of work on inland waters. CBD parties, in their separate development and adoption of their other biome and crosscutting programs of work, have paid much less attention to the relevance of wetland management in notably coastal and nearshore marine systems and in protected areas in relation to the designation and management of Wetlands of International Importance (Ramsar Sites). Only recently has the CBD given improved recognition to the relevance of Ramsar's lead implementation role for these matters, in its protected areas and marine and coastal biodiversity programs of work (CBD COP10 Decision X/31 on Protected Areas, http://www.cbd.int/decision/cop/?id=12297 and Decision X/29 on marine and coastal biodiversity http://www.cbd.int/decision/cop/?id=12295). An assessment of the interconnectivity between the CBD inland waters and marine and coastal programs of work (SCBD 2011) revealed that there is remarkably little linkage on common issues across the two programs and that the compartmentalized approach of the biome programs of work, as a major approach to CBD implementation, appears to hinder and run counter to the application of CBD's overarching ecosystem approach, which explicitly requires landscape and seascape scale cross-sectoral and integrated approaches to conservation and sustainable use, whereas the approach is embodied in Ramsar's definition of "wise use" (Ramsar Convention Secretariat 2005). For further discussion of "wise use" in relation to CBD's "ecosystem approach," see Finlayson et al. (2011). This lack of coherence between CBD's programs of work, or rather the failure to systematically use the ecosystem approach and not programs of work as the point of entry, further exacerbates problems with selective cross-referencing to wetland management and the role and guidance of the Ramsar Convention. Recent attention to the Strategic Plan for Biodiversity (2011–2020) and its Aichi Biodiversity Targets should help address these, and other, challenges to the improved recognition in practice of the role of wetland management.

Introduction: The Origins and Purpose of the Strategic Plan for Biodiversity 2011–2020

The Strategic Plan for Biodiversity 2011–2020 was adopted at the tenth meeting of the Conference of the Parties to the **Convention on Biological Diversity** in 2010 (SCBD 2010). Its purpose is to promote effective implementation of action on biodiversity by all parties and stakeholders as well as providing a flexible framework for the establishment of national and regional biodiversity-related targets. It is also recognized as the overarching flexible framework relevant to the objectives of all the **biodiversity-related conventions. The Convention on Wetlands** (**Ramsar**), for example, recognizes the important contribution of its strategic plan toward the achievement of the Strategic Plan for Biodiversity 2011–2020 (Ramsar Secretariat 2012).

The rationale for the Strategic Plan for Biodiversity 2011–2020 is that biological diversity underpins ecosystem functioning and the provision of ecosystem services essential for human well-being: it provides for food security, human health, the provision of clean air and water, contributes to local livelihoods, and economic development, and is essential for the achievement of the **Millennium Development Goals**, including poverty reduction. The **vision** for the plan is: “Living in Harmony with Nature” where “By 2050, biodiversity is valued, conserved, restored and wisely used, maintaining ecosystem services, sustaining a healthy plant and delivering benefits essential for all people.” Its **mission** is to “take effective and urgent action to halt the loss of biodiversity in order to ensure that by 2020 ecosystems are resilient and continue to provide essential services, thereby securing the planet’s variety of life, and contributing to human well-being, and poverty eradication.”

The Aichi Biodiversity Targets

The achievement of the vision and mission of the Strategic Plan for Biodiversity 2011–2020 requires pressures on biodiversity be reduced, ecosystems restored, biological resources used sustainably and benefits of genetic resources shared in a fair and equitable manner, adequate financial resources be provided, capacities enhanced, biodiversity issues and values mainstreamed, appropriate policies be effectively implemented, and decision-making be based on sound science and the precautionary approach. Such principles are reflected in five strategic goals accompanied by 20 “Aichi Biodiversity Targets” (so named because they were adopted in Aichi Prefecture in Japan):

Strategic Goal A: Address the Underlying Causes of Biodiversity Loss by Mainstreaming Biodiversity Across Government and Society

Target 1
By 2020, at the latest, people are aware of the values of biodiversity and the steps they can take to conserve and use it sustainably.

Target 2
By 2020, at the latest, biodiversity values have been integrated into national and local development and poverty reduction strategies and planning processes and are being incorporated into national accounting, as appropriate, and reporting systems.

Target 3
By 2020, at the latest, incentives, including subsidies, harmful to biodiversity are eliminated, phased out, or reformed in order to minimize or avoid negative impacts, and positive incentives for the conservation and sustainable use of biodiversity are developed and applied, consistent and in harmony with the convention and other relevant international obligations, taking into account national socioeconomic conditions.

Target 4
By 2020, at the latest, governments, business, and stakeholders at all levels have taken steps to achieve or have implemented plans for sustainable production and consumption and have kept the impacts of the use of natural resources well within safe ecological limits.

Strategic Goal B: Reduce the Direct Pressures on Biodiversity and Promote Sustainable Use

Target 5
By 2020, the rate of loss of all natural habitats, including forests, is at least halved and where feasible brought close to zero, and degradation and fragmentation is significantly reduced.

Target 6
By 2020 all fish and invertebrate stocks and aquatic plants are managed and harvested sustainably, legally, and applying ecosystem based approaches, so that overfishing is avoided, recovery plans and measures are in place for all depleted species, fisheries have no significant adverse impacts on threatened species and vulnerable ecosystems, and the impacts of fisheries on stocks, species, and ecosystems are within safe ecological limits.

Target 7

By 2020 areas under agriculture, aquaculture, and forestry are managed sustainably, ensuring conservation of biodiversity.

Target 8

By 2020, pollution, including from excess nutrients, has been brought to levels that are not detrimental to ecosystem function and biodiversity.

Target 9

By 2020, invasive alien species and pathways are identified and prioritized, priority species are controlled or eradicated, and measures are in place to manage pathways to prevent their introduction and establishment.

Target 10

By 2015, the multiple anthropogenic pressures on coral reefs and other vulnerable ecosystems impacted by climate change or ocean acidification are minimized, so as to maintain their integrity and functioning.

Strategic Goal C: To Improve the Status of Biodiversity by Safeguarding Ecosystems, Species, and Genetic Diversity

Target 11

By 2020, at least 17% of terrestrial and inland water and 10% of coastal and marine areas, especially areas of particular importance for biodiversity and ecosystem services, are conserved through effectively and equitably managed, ecologically representative, and well-connected systems of protected areas and other effective area-based conservation measures and integrated into the wider landscapes and seascapes.

Target 12

By 2020 the extinction of known threatened species has been prevented, and their conservation status, particularly of those most in decline, has been improved and sustained.

Target 13

By 2020, the genetic diversity of cultivated plants and farmed and domesticated animals and of wild relatives, including other socioeconomically as well as culturally valuable species, is maintained, and strategies have been developed and implemented for minimizing genetic erosion and safeguarding their genetic diversity.

Strategic Goal D: Enhance the Benefits to All from Biodiversity and Ecosystem Services

Target 14

By 2020, ecosystems that provide essential services, including services related to water, and contribute to health, livelihoods, and well-being, are restored and safeguarded, taking into account the needs of women, indigenous and local communities, and the poor and vulnerable.

Target 15

By 2020, ecosystem resilience and the contribution of biodiversity to carbon stocks has been enhanced, through conservation and restoration, including restoration of at least 15% of degraded ecosystems, thereby contributing to climate change mitigation and adaptation and to combating desertification.

Target 16

By 2015, the Nagoya Protocol on Access to Genetic Resources and the Fair and Equitable Sharing of Benefits Arising from their Utilization is in force and operational, consistent with national legislation.

Strategic Goal E: Enhance Implementation Through Participatory Planning, Knowledge Management, and Capacity Building

Target 17

By 2015 each party has developed, adopted as a policy instrument, and has commenced implementing an effective, participatory, and updated national biodiversity strategy and action plan.

Target 18

By 2020, the traditional knowledge, innovations, and practices of indigenous and local communities relevant for the conservation and sustainable use of biodiversity, and their customary use of biological resources, are respected, subject to national legislation and relevant international obligations, and fully integrated and reflected in the implementation of the convention with the full and effective participation of indigenous and local communities, at all relevant levels.

Target 19

By 2020, knowledge, the science base and technologies relating to biodiversity, its values, functioning, status and trends, and the consequences of its loss, are improved, widely shared and transferred, and applied.

Target 20

By 2020, at the latest, the mobilization of financial resources for effectively implementing the Strategic Plan for Biodiversity 2011–2020 from all sources, and in accordance with the consolidated and agreed process in the Strategy for Resource Mobilization, should increase substantially from the current levels. This target will be subject to changes contingent to resource needs assessments to be developed and reported by parties.

Wetlands and the Strategic Plan for Biodiversity 2011–2020 and Aichi Biodiversity Targets

By and large the Strategic Plan for Biodiversity 2011–2020 is not biome or sector based, and wetlands are therefore not specifically mentioned, with the exception of “coral reefs” in target 10, but the Strategic Plan for Biodiversity 2011–2020 and its Aichi Biodiversity Targets apply equally to wetlands. For example, the term "biodiversity" in the Strategic Plan and its Aichi Targets includes, of course, all wetland-dependant species, and likewise "ecosystem" includes wetlands as ecosystems. Because of the role of wetlands in underpinning **water-related ecosystem services**, they also play a crosscutting role. The Strategic Plan for Biodiversity 2011–2020 also recognized the paramount importance of water as an ecosystem service (in its footnote 15). CBD COP-10 also recognized the clear basis to strengthen attention to water across all relevant interests and programs of work of the convention (SCBD 2010), and CBD COP-11 (2012) recognized the importance of the water cycle to achieving most of the Aichi Biodiversity Targets, requiring that the water cycle be considered as a crosscutting theme when implementing the Strategic Plan for Biodiversity 2011–2020 (SCBD 2012).

The Strategic Plan for Biodiversity 2011–2020 lays an improved framework facilitating enhanced collaboration including between all of the biodiversity-related multilateral environment agreements (MEAs). The improved recognition of water as an ecosystem service also significantly increases resonance between the strategic plan, and hence the MEAs, and the significant broader social, economic, and political interest in water.

Further details of the relationship between the CBD, wetlands, and the Ramsar Convention are provided in contribution CBD and wetland management.

Future Challenges

There are significant constraints to implementation of the plan and the achievement of the targets. Approaches to, and policies for, land and water use remain significantly fragmented and sector-based interests still dominate. To a large extent, the Aichi Biodiversity Targets require collective actions implemented at the landscape scale. This remains a significant challenge and the strategic plan is weak on guidance as to how this can be better achieved. Most of all, the key drivers of biodiversity loss, and in this case wetlands loss and degradation, are indirect including population growth, unsustainable consumption and production patterns, and inappropriate economic models and approaches (which externalize ecosystem values and benefits). Unless these, and other drivers, are addressed, moving society toward improved sustainability of natural resources, including land and water, and more equitable resource use, it will not be possible to adequately reduce the direct drivers of biodiversity loss (such as pollution, water extraction, and habitat conversion). Assessments suggest that it is possible to meet human needs for resources on a more sustainable and equitable footing – but significant shifts in policies and approaches are required to do this. Recognizing the role of ecosystems in sustaining natural resource availability, in this case in particular regarding water, will be a significant step toward redressing the current imbalance between ecosystem and development interests.

Transactional and Regional Legal Frameworks

59

Sacha Kathuria and Kirk W. Junker

Contents

Abstract

Wetlands are governed not only by domestic law, but by transnational and regional legal frameworks as well. These transnational and regional legal tools should be considered as part of the overall legal regime for wetlands. Sometimes domestic wetlands law exists in order to comply with transnational or regional agreements. This article sets out to describe transnational sources of law and the nature of global problems that they are meant to remedy. After identifying these sources of law are, important examples are provided. As in other areas of international law, custom and principle also provide important sources of law for protecting and maintaining wetlands.

Introduction

While domestic law, enabled by the sovereignty of the state, may well establish norms through the legal instruments of statutes, regulations, and the ensuing permits the geographic reach of those norms cannot extend beyond the state's own borders. Thus, when it comes to wetland management, a wetland's expanse or recharging area over more than one state can lead to the need for cooperation between and among the states concerned. The agreement of states is often recorded in treaties, conventions, or other types of international agreements. Moreover, if one considers a wetland's effect on ecosystems beyond its immediate recharging area, wetlands, like rivers, may eventually be determined to be best managed as the common property of all mankind, just as the oceans and seas are already.

Transnational Frameworks

Before examining how transnational frameworks work with regard to wetland management, one must understand the nature of the framework system. The mechanism through which international frameworks are crafted is the treaty. Treaties "are described as conventions, agreements, protocols, covenants, pacts, etc." (Guruswamy 2007). It is also important to note that the name of an agreement between or among states "is not decisive" (Aust 2010). Thus, calling an agreement a "treaty," "convention," or other name does not determine whether it is binding on the signatory states.

This also applies to framework conventions. Like all other international legal agreements, one must read the intent of the states, as expressed in the document, to determine its legal nature. One might imagine the term "framework" being applied to any legal structure. However, as a term of art, legal "framework" most often refers to framework conventions. "There is no fixed model for framework agreements and the term does not have a technical meaning" (Bodansky, as cited by Matz-Lueck 2013). The term "treaty" "suggests the most formal kind of agreement" (Brierly 1963). They can be bilateral, regional, or multilateral. The Vienna Convention, commonly referred to as the "treaty on treaties" defines a treaty as "an international agreement, concluded between States in written form and governed by international law, whether embodied in a single instrument or two or more related instruments and whatever its particular designation" (Vienna Convention, Article 2 1969).

Treaties, "serve as international legislation, or they may have the character of contracts between members of the international community" (McCaffrey 2006). Multilateral treaties serve as law-making "machinery" for the purpose of adapting international law "to new conditions and in general for strengthening the force of the rule of law between states" (Brierly 1963). Treaties are like contracts in the sense that "they derive their validity from the agreement of the parties" (Jessup 1959). Signatories to treaties are expected to follow the principle of *pacta sunt servanda*, i.e., agreements are binding and once agreed to, should be ratified or otherwise carried out in good faith. However, what makes the treaty particularly unique is its reservation option, which allows countries signing to opt out of certain provisions. According to the Vienna Convention, the reservation option is "a unilateral statement, however phrased or named made by a State [. . .] whereby it purports to exclude or modify the legal effect of certain provisions of the treaty in their application to that State" (Vienna Convention, Article 2 1969). A reservation does not require acceptance by other contracting states "unless the treaty so provides" (Vienna Convention, Article 20 1969). Once signed, a treaty may be self-executing or it may require a ratification process, depending upon the constitutional process of each country (Jessup 1959).

The framework convention has become a common multilateral treaty form, together with more specific protocols, in accomplishing the goals of states, especially in the field of environmental law, to which one can say that wetlands law belongs. "The regulation of international issues by framework conventions is a relatively recent regulatory technique in international law and has mainly been employed in the field of international environmental law. Framework agreements are usually associated with the so-called 'framework convention and protocol approach' by which parties agree on a more general treaty, the framework convention, and more detailed protocols to fill out the room left by the legal framework for specific regulations" (Matz-Lueck 2009). But even if the form of framework conventions turns out to be similar, it is not so by some sort of agreement or requirement. Therefore, one must use an inductive method of observation and usage to understand what is meant by the term. A quick review of the United Nations' framework conventions would yield such large and well-known examples as The UN Framework Convention on Climate Change (UNFCCC), The World Health Organizations Framework Convention on Tobacco Control, and The Framework Convention for the Protection of National Minorities, but also the lesser-known and very specific 2004 Framework Convention instituting cooperation for transboundary development relating to the Esch-Belval project between the Government of the French Republic and the Government of the Grand Duchy of Luxembourg.

Transnational denotes a global character, going beyond the reach of a country or region. Therefore, transnational or multilateral frameworks are global agreements that can serve the interests of the international community. Unlike regional frameworks, they are not meant for any certain geographic or cultural group. Nor are they provincial. Rather, they address concerns of international importance. Conservation of wetlands is one such international concern. Wetlands are a source of "economic, cultural, scientific, and recreational value," and their demise "would be irreplaceable" (Ramsar Convention 1975). Though there are several transnational frameworks affecting wetland management, three of the most pertinent will be discussed here: the Ramsar Convention, the Convention on Biological Diversity, and the Convention on Migratory Species. This purpose here is not to provide an all-inclusive list of transnational frameworks. The purpose here is to provide an overview of how a few of the most significant transnational frameworks affect wetland management through their objectives, mechanisms, and enforcement.

The objective of a transnational framework is to address a particular issue affecting the international community. International cooperation and consensus with regard to environmental issues is of special importance because one country's actions may dramatically affect the environment of its neighbors or indeed the entire world. Wetlands are affected by a variety of transboundary environmental factors, from air quality, species diversity, and migration to desertification. The main themes throughout the treaties examined here are the conservation of wetlands, biodiversity, and migratory species.

Other Sources of International Law

Treaties are not the sole source of international law. A legal framework should be understood to include other sources of law. According to Article 38 of the International Court of Justice Statute, primary sources of international law not only include international conventions but also international custom and general principles of law (International Court of Justice Statute, Article 38 1945). Customary law results from two components. The first is regarded as objective and is evidenced by general and consistent state practices. The second is regarded as subjective and is evidenced by the belief in a sense of legal obligation which is also called the *opinio juris*. General principles are those that are common to major legal systems and may be invoked as supplementary rules of international law (Yearbook 1950). The importance of a transnational framework is not diminished even if all countries do not accede to it. As Stephen McCaffrey explains, "A treaty may attract state practice which, when accompanied by *opinio juris*, eventually crystallizes into a norm of customary international law that binds even states that are not parties to the treaty" (McCaffrey 2006). This means that even if a state has not acceded to a treaty affecting wetland management, it may nonetheless be bound by it through other forms of international law. In practice, in the case of custom, this can mean that when a conflict arises between states, a state can be bound by its past practices. It also means, in the case of principle, that a state can announce an intended form of legal behavior to which it can be bound, even if it has not signed an agreement with another state or states to do so.

As to the situations when domestic law and international law conflict, the Vienna Convention on the Law of Treaties, operating as the rule book of treaties, states in Article 27 that "[a] party may not invoke the provisions of its internal law as justification for its failure to perform a treaty. This rule is without prejudice to Article 46" (Vienna Convention, Article 27 1969). Article 46, in turn, provides that "(1) A State may not invoke the fact that its consent to be bound by a treaty has been expressed in violation of a provision of its internal law regarding competence to conclude treaties as invalidating its consent unless that violation was manifest and concerned a rule of its internal law of fundamental importance. (2) A violation is manifest if it would be objectively evident to any State conducting itself in the matter in accordance with normal practice and in good faith" (Vienna Convention, Article 46 1969).

The Convention on Wetlands of International Importance especially as Waterfowl Habitat, commonly referred to as the Ramsar Convention, is the most significant transnational legal framework directly addressing the wetlands. Signed in Ramsar, Iran on February 2, 1971 and entered into force on December 21, 1975, it seeks "to stem the progressive encroachment on and loss of wetlands" by "combining far-sighted national policies with co-ordinated international action" (Ramsar Convention 1975). Ramsar is the first treaty with the principal objective to protect a particular type of ecosystem (Bowman 1999). Ramsar defines wetlands as "areas of marsh, fen, peatland or water, whether natural or artificial, permanent or temporary, with water that is static or flowing, fresh, brackish or salt, including areas of marine water the depth of which at low tide does not exceed six metres" (Ramsar Convention, Article 1 1975). It also considers waterfowl birds ecologically dependent on wetlands (Ramsar Convention, Article 1 1975).

Biodiversity is an important concept not only to wetlands but also to all ecosystems. The Convention on Biological Diversity (CBD) took effect on December 29, 1993 and defines biodiversity as "the variability among living organisms from all sources [. . .] and the ecological complexes of which they are a part: this includes diversity within species, between species and of ecosystems" (CBD, Article 2 1993). Its purpose is to "conserve biological diversity, the sustainable use of its components and the fair and equitable sharing of the benefits arising out of the utilization of genetic resources" (CBD, Article 1 1993). Sustainable use is "the use of components of biological diversity in a way and at a rate that does not lead to the long-term decline of biological diversity" (CBD, Article 2 1993).

As the Ramsar Convention indicates, migratory species such as waterfowl birds are an important component to the wetland ecosystem. The Convention on the Conservation of Migratory Species of Wild Animals (CMS or Bonn Convention) signed in Bonn, Germany and entered into force on November 1, 1983 is "to take action to avoid any migratory species becoming endangered" (CMS Convention, Article 2 1983). Migratory species are defined as "the entire population or any geographically separate part of the population of any species or lower tax of wild animals, a significant portion of whose members cyclically and predictably cross one or more national jurisdictional boundaries" (CMS Convention, Article 1 1983).

Achieving the Objectives of International Frameworks

Once a framework objective is agreed upon, countries need to decide how they will achieve their goals. Some frameworks are better than others in identifying mechanisms. While all frameworks state that something can be done to combat the problem at hand, often times they are vague and lofty. This may be partially due to the sheer size of participation in a transnational framework. Taking into account all the different challenges, viewpoints, and attitudes from around the world, the more generalized the mechanisms, the more free contracting parties are to interpret them to suit their needs. It is therefore up to the contracting parties of the transnational treaty to take concrete action to ensure objectives of the framework are met. Each contracting party can take steps domestically, such as through national legislation, public awareness, and education, to achieve framework objectives.

Ramsar seeks to attain its objectives through the "wise use" of wetlands. Wise use is the maintenance of ecological character, "achieved through the implementation of ecosystem approaches, within the context of sustainable development" (Ramsar Introductory 2008). Ramsar also requires contracting parties to designate wetlands within their respective territories to be on a List of Wetlands of International Importance (also called the Ramsar List) (Ramsar Convention, Article 2 1975). The contracting parties are to formulate plans to promote conservation of sites on the Ramsar List and to share information regarding any changes to the ecological character of any such sites. (Ramsar Convention, Articles 3 and 2 1975). They are also to consult with each other about implementing objectives especially as they pertain to international wetlands (Ramsar Convention, Article 5 1975).

Parties to the Convention on Biological Diversity (CBD) agree to cooperate with each other and to develop national strategies to attain the goals of the framework (CBD Articles 5 and 6 1993). Each country is expected to identify components of biological diversity, monitor them, identify processes that negatively impact conservation and sustainable use, and maintain and organize identification and monitoring activities, (CBD, Article 7 1993). The CBD specifically refers to *in situ* conservation in Article 8, which is the conservation of "ecosystems and natural habitats and the maintenance and recovery of viable populations of species in their natural surroundings" or "where they have developed their distinctive properties" (Article 2, CBD 1993). Contracting parties to the CBD are to establish systems of protected areas for *in situ* conservation and regulate, promote, rehabilitate, and prevent the eradication of such ecosystems (CBD, Article 8 1993). Likewise, in an effort to complement *in situ* conservation, contracting parties should also adopt measures for *ex situ* conservation by adopting measures for conservation. *Ex situ* conservation is the "conservation of components of biological diversity outside their natural habitats" (CBD, Article 8 1993). This means establishing and maintaining facilities for research, creating measures for the reintroduction of threatened species into their natural habitats, and by cooperating financially to facilities in developing countries (CBD, Article 9 1993).

Contracting parties to the CBD are to carry out these expectations by offering incentives in their respective countries to comply with sustainability and conservation, and provide research, training, public education, and awareness (CBD, Articles 11, 12, 13 1993). Each country is expected to take an assessment and minimize adverse impacts of projects, programs, and policies on biodiversity (CBD, Article 14 1993). In addition to developing national policies and legislation, contracting parties to the CBD agree to cooperate together on creating access to genetic resources, transferring technology, and exchanging information (CBD Articles 15, 16, 17, 18 1993). Moreover, they are expected to engage in biotechnological research and provide financial support to initiatives within their capabilities (CBD, Articles 19 and 20 1993).

The Convention on Migratory Species measures the success of conservation efforts by gleaning whether migratory species are maintaining themselves on a long-term basis, if their range is being reduced, the ability of sufficient habitat in the long-term, and whether the distribution and abundance of migratory species is consistent with suitable ecosystems and wise wildlife management (CMS Convention, Article 1 1983). Parties to CMS are to cooperate in research relating to migratory species, provide immediate protection for them, and conclude agreements covering the conservation and management of migratory species (CMS Convention, Article 3 1983). This can be done through the conservation and restoration of habitats of endangered species and the prevention of activities and situations that threaten migratory species (CMS Convention, Article 3 1983). Furthermore, "Range States" under CMS, that is, states that have jurisdiction over a range of migratory species, are expected to conclude agreements that benefit species and give them priority (CMS Convention, Article 3 1983). As used in the CMS Convention, "arguments" "means international agreements relating to the conservation of one or more migratory species" (CMS Convention, Article 1 1983).

While negotiating and developing a framework of any kind is difficult, perhaps the most challenging part is enforcing the agreement. This is especially true with environmental frameworks on a large, transnational scale. It is inevitable that some countries will be better than others at enforcement. Much of this has to do with wealth, threat perception, and the rule of law. Ultimately enforcement is up to each individual state.

Perhaps because it is an older treaty, Ramsar does not provide for strict enforcement mechanisms. Nevertheless, Ramsar has modernized itself through the issuance of a Management Guidance Procedure and the development of the Wetland Conservation Fund to help finance small conservation projects. The CBD and CMS take into account the possibilities of disputes between contracting parties. Failure to live up to terms of frameworks affects all parties. Annex II of the CBD provides for arbitration and conciliation procedures for contracting parties in case of a dispute. (CBD, Annex II 1993). Article 13 of the CMS calls for negotiation between contracting parties in case two or more parties are in a dispute. If the dispute is still not resolved, then by mutual consent, parties are advised to submit the dispute to the Permanent Court of Arbitration at The Hague. (CMS, Article 13 1983).

Transnational frameworks are an important part of international environmental law and indeed wetland management. They provide a forum for several diverse countries to combat some of the most difficult issues affecting humankind. While transnational frameworks may sometimes be vague in an effort to appease all parties, they nonetheless bring important problems to the forefront of international consciousness and help contracting parties develop solutions. Although enforcement is often elusive, dispute resolution efforts and negotiation provide a means of overcoming this persistent hurdle.

Regional Agreements

"Regions" is a legal category for public international law that has historically been understood to mean something more than one state, but less than all states (or approximately all states.) There are regional conventions for trade, exploitation of natural resources, prosecution of crime, and environmental protection. Thinking about regional agreements requires that one think about why such a species of agreement should exist. Why not solve wetlands problems through the establishment of the most wide-reaching norm possible, as would be done with a transnational agreement like the UNFCCC? The mantra of "think globally, act locally" addresses two polar positions of legal thinking. As an alternative to these polar positions of global and local, when should one think regionally or act regionally, specifically when it comes to wetlands protection, management, or creation? A first answer would be tied to the object of concern – the wetland itself. The recharging area of a wetland, like so many other natural phenomena of environmental law, may well be spread over more than one state. What is perhaps more interesting, however, is that states should want to come together because they recognize that the protection, management, and creation of wetlands is a concern common to all residents of the earth. It is not difficult to provide a catalogue, even if incomplete, of the extant regional wetlands agreements. Therefore, what can one say is common to the regional agreements that gives them their own character? A survey might show that they affect only interested states, whereas a transnational agreement might be signed and ratified by states which agree with the norms, but which do not directly experience the effects of those norms, because the problems covered have yet to arise in those states.

Regional agreements are typified, as their name says, by applying to a particular and limited geographic region. (See, for example The North American Wetlands Conservation Act 1989, The African-Eurasian Waterbird Agreement 1995, The African Convention on the Conservation of Nature and Natural Resources 2003, The Revised Southern African Development Community (SADC) Protocol on Shared Watercourse Systems 1985, revised 2000 [SADC Protocols are legally binding among members], The South Africa DC Protocol on Fisheries 2001, or The South Africa DC Protocol on Forestry 2002).

It is not only the case, however, that a regional agreement is drafted by and applies to a limited set of states for a limited purpose, such as wetland management and related issues. The European Union, for example, while unique in its vision of a modicum of shared sovereignty, is nevertheless held together by a set of regional agreements that when seen on the whole, create a complete government structure in all branches of government with competencies in nearly all areas of legislation. The European Union's legal instruments concerning wetlands include the European Union Habitats Directives Annex 1 (92/43/EC), The European Union Water Framework Directive (2000/60/EC), The European Union Birds Directive (2009/147/EC), The European Commission's Communication "Flood Risk Management: Prevention, Protection, Mitigation" of 12 July 2004, or Council Directive on the Conservation of Wild Birds (2009/147/EC). It should be here mentioned that for better or worse, it has been noted that the African Union, successor to the Organization of African Unity, has often copied European legal institutional structures and practices.

In addition there are European regional agreements that are not part of the Union's shared-sovereignty competencies and just happen to be entered into by a subset of states on the European continent. The European regional agreements that are not part of the European Union's competencies include The Barcelona Convention (signed February 16th, 1976, in force February 12th, 1978, and revised in Barcelona, Spain on June 10th, 1995 as the Convention for the Protection of the Marine Environment and the Coastal Region of the Mediterranean), the Bonn

Convention on the Conservation of Migratory Species of Wild Animals of 1983, the Convention on Cooperation for the Protection and Sustainable Use of the Danube River of 1994, the Programme on the Sustainable Development of the Rhine 2001, also known as “Rhine 2020,” The Agreement on Conservation of Seals in the Wadden Sea 1990, The Agreement on the Conservation of Small Cetaceans of the Baltic and North Seas 1991, and The Agreement on the Conservation of Cetaceans of the Black Sea, Mediterranean Sea, and Contiguous Atlantic Area 1996.

Chapter VIII of the United Nations Charter enables member states to enter into Regional Agreements. Without this explicit permission, one might have argued that a United Nations member state could act only in concert with all other United Nations member states. Within Chap. VIII, Article 52 and subsequent articles focus exclusively upon agreements concerning peace and conflict, however, and neither mention the environment or biodiversity in general nor wetlands in particular. To that end, Chap. VIII is largely designed to be permissive rather than restrictive; that is, it allows United Nations member states to enter into regional agreements.

Regional agreements are concluded with respect to political, economic, military, scientific, technical, and cultural matters. A literature review of regional agreements will demonstrate that much has been written on the nature, advantages, and disadvantages of regional trade agreements. The Organization of Economic Cooperation and Development notes that in the first 11 years of the World Trade Organization, the number of regional trade agreements notified to the World Trade Organization alone tripled from 58 to 188 in number (OECD 2013). The Organization of Economic Cooperation and Development divides the lessons that we can learn from regional trade agreements as follows: “[t]he first lesson is that many consequences of regional trade agreements activity bolster the case for a strengthened multilateral framework” (OECD 2013). According to the Organization of Economic Cooperation and Development, “[t]his applies particularly to the contribution of regionalism to divergence from the rules of the multilateral system, to the effects which the patchwork of regionalism can have on non-members of those agreements and to the role of regionalism in raising transaction costs for business” (OECD 2013). The second lesson, according to the Organization of Economic Cooperation and Development, is that there are features of regional approaches that complement multilateral agreements or even be drawn upon in designing strengthened multilateral rules. “The scope for complementarity arises from the contribution which regional initiatives can make towards harmonisation of rule making; the scope for drawing upon arises from the extent to which Regional Trade Agreements (RTAs) go beyond the WTO. Together, these two elements have yielded highly effective synergies between approaches at the regional and the multilateral levels” (OECD 2013).

Transnational and Regional Agreements

The interplay between transnational and regional wetland agreements has not been studied in such detail and the question as to whether the same observations the Organization for Economic Cooperation and Development made of trade agreements can be said to apply to wetlands agreements remains unanswered. At least from trade agreements one can observe that it is possible that regional agreements may both diverge from multilateral agreements and be used to strengthen multilateral agreements. Like transnational legal frameworks, regional legal frameworks are an important part of international environmental law, biodiversity protection, and wetland management. Some of the vagueness of transnational frameworks may be alleviated in regional frameworks by including only affected parties to the wetlands protection scheme.

Waterbird Flyways and History of International Cooperation for Waterbird Conservation

60

Nick C. Davidson and David A. Stroud

Contents

Abstract

Many waterbirds are migratory along flyways which connect their breeding, staging and non-breeding areas, and for conservation purposes can be considered under single-species migration systems, multispecies flyways and global regions for waterbird conservation management. There are different types of flyway-scale initiatives: facilitative, formal or legally binding; bilateral or multilateral. A wide range of outcomes are sought through international flyway cooperation, but there are continuing major challenges to achieving successful migratory waterbird conservation.

Waterbird Flyways

Flyways can be considered at different scales.

Single species migration systems: the distributional extent of the annual migration of a species, or a population within a species, encompassing breeding, staging and nonbreeding areas. While often described as the flyways of the species concerned, such annual distributional ranges are better described as the migration system of the species concerned.

Multispecies flyways: as defined by the Ramsar Convention on Wetlands:"*A single flyway is composed of many overlapping migration systems of individual waterbird populations and species, each of which has different habitat preferences and migration strategies. From knowledge of these various migration systems it is possible to group the migration routes used by waterbirds into broad flyways, each of which is used by many species, often in a similar way, during their annual migrations*." This definition was developed by the International Wader Study Group (IWSG 1998) and subsequently adopted by the Ramsar Convention (Ramsar Convention 1999).

Research into the migrations of many wader or shorebird (Charadrii) species, for example, indicates that the migrations of waders can broadly be grouped into eight flyways (Fig. 1). However, it is important to note that these flyways apply only to waders/shorebirds and not to other waterbird taxa – although this graphic has been widely, but erroneously, used for all waterbirds, particularly by the media in relation to highly pathogenic avian influenza (HPAI) issues.

Global regions for waterbird conservation management: At a larger scale still are global regions containing species with similar migration systems that are the

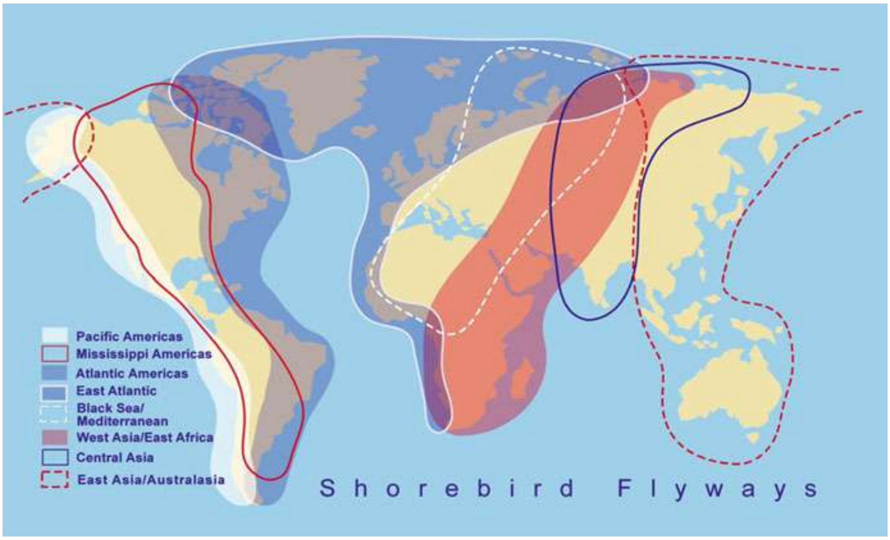

Fig. 1 Wader (shorebird) flyways (Redrawn from IWSG (1998))

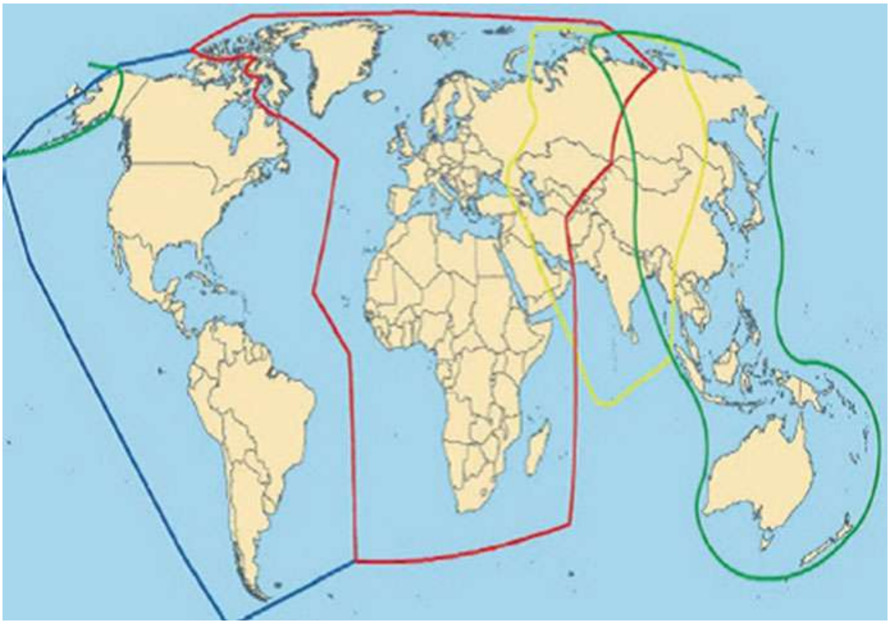

Fig. 2 The main "geopolitical" flyways for waterbird conservation (From Global Interflyway Network (2012))

subject (actual or potential) of shared international conservation activity, i.e., "geo-political flyways" (Fig. 2). Thus, the agreement area for the African-Eurasian Agreement on the conservation of migratory waterbirds (AEWA) is the area that contains the migration systems of all migratory waterbirds that occur in Africa and western Eurasia. A similar approach has been applied to the main flyway systems of the Asia-Pacific region. lt contains multiple flyways of different waterbird taxa, and its value is in terms of the political and governmental processes of international cooperation.

What Are Waterbirds?

Waterbirds are those species which are ecologically dependent on wetlands, for all or part of their annual cycle. As defined by Ramsar Convention (Ramsar Convention 1999), this can include any wetland bird species, but at the broad level of taxonomic order it includes especially:

- Penguins: *Sphenisciformes*
- Divers: *Gaviiformes*
- Grebes: *Podicipediformes*

(*continued*)

- Wetland related pelicans, cormorants, darters, and allies: *Pelecaniformes*
- Herons, bitterns, storks, ibises, and spoonbills: *Ciconiiformes*
- Flamingos: *Phoenicopteriformes*
- Screamers, swans, geese, and ducks (wildfowl): *Anseriforme*s
- Wetland-related raptors: *Accipitriformes* and *Falconiformes*
- Wetland-related cranes, rails, and allies: *Gruiformes*
- Hoatzin: *Opisthocomiformes*
- Wetland-related jacanas, waders (or shorebirds), gulls, skimmers, and terns: *Charadriiformes*
- Coucals*: Cuculiformes*
- Wetland-related owls: *Strigiformes*

Many species in other bird orders and families are also recognized as "wetland dependent" because of their ecological dependence on wetlands. Although there is no standard global list of such species, see BirdLife International (2002) and Crosby and Chan (2005) for lists of such species for Africa and Asia, respectively.

Several other terms are in wide use for different groups of waterbirds. These include:

- **Shorebirds**: A term increasingly used for species in the order Charadriiformes (excluding seabirds) such as plovers, sandpipers, oystercatchers, stilts and avocets. In some parts of the world these species are called **waders**.
- **Wading birds**: species of long-legged waterbirds such as herons and egrets, ibises, storks, cranes and flamingos. Confusingly, in North America these species are sometimes referred to as "waders."
- **Wildfowl**: species of ducks, geese and swans in the family Anatidae.
- **Waterfowl**: often now treated as a term synonymous with "waterbirds," but in North America usually covers only species in the order Anseriformes.

The terms wildfowl and waterfowl have hunting connotations, "fowling" being an old word for hunting birds, so these terms have often been used when referring to those species of waterbirds which are, or have been, quarry species.

For research and conservation purposes, waterbirds are often grouped in **guilds**: groups of species with similar ecology (most often feeding ecology) and morphology. There is no standard suite of waterbird guilds. Rather, each researcher has defined one or more such guilds based on the waterbird species composition at a wetland, but they typically include groupings such as:

(*continued*)

- *Herbivores or omnivores feeding in sheltered, shallow water* (e.g., ducks and swans)
- *Diving waterbirds* (mostly fish-eating: e.g., divers, cormorants, darters, pelicans, some seabirds)
- *Wading birds*: long-legged species feeding in shallow waters (e.g., herons and egrets, ibises, storks, cranes and flamingos, and some shorebirds such as stilts and avocets)
- *Omnivores and insectivores* feeding in dense vegetation on wetland margins (e.g., coots, gallinules, and rails)
- *Species feeding on shorelines and in sheltered, shallow waters*, often in tidal areas (e.g., shorebirds)
- *Fish-eating and scavenging waterbirds,* feeding along the shoreline and on the surface of shallow waters (e.g., gulls and terns)
- *Wetland-dependent raptors* (e.g., Osprey, sea-eagles, some harriers)

Waterbird Flyway Conservation Initiatives

There are different categories of flyway initiative. They may be facilitative, formal, or legally binding; some are bilateral, others multilateral. In general, the development of different waterbird flyway "initiatives" has followed a similar pathway, illustrated in Fig. 3.

Flyway initiatives have a long history, some dating back to the early twentieth century, although most have been developed since the early 1970s (Fig. 4).

What do such initiatives try to achieve? Generally a range of outcomes, including:

- High-level acknowledgment of shared international heritage/resources
- Agreement by governments on common conservation objectives and goals (leading to common policies and laws (e.g., lists of protected species) and joint actions)
- Establishing international standards for national conservation action
- Data and information exchange
- Formal transboundary cooperation (e.g., for Ramsar Sites)
- Joint working/surveys/monitoring
- Joint funding of international scale initiatives

Working with governments, international and national NGOs have played, and continue to play, key roles in flyway initiatives, including:

- *Initiating* (e.g., Ramsar Convention, Convention on Biological Diversity)
- *Supporting* (e.g., Ramsar's International Organization Partners) through providing access to science

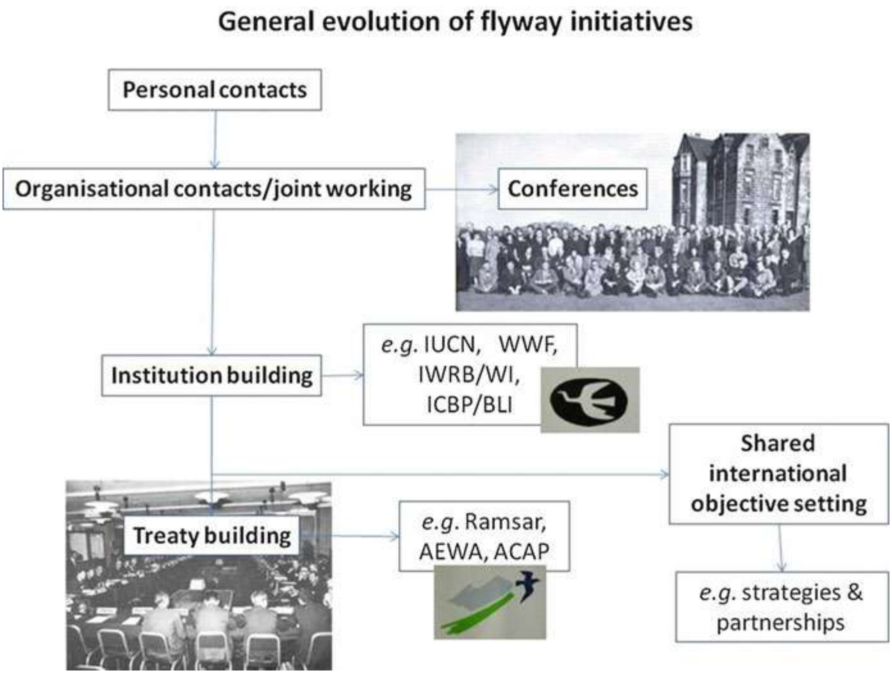

Fig. 3 The general evolution of waterbird flyway initiatives (From: Davidson and Stroud in Global Interflyway Network (2012))

- *Facilitating* (e.g., encouraging formal transboundary cooperation)
- *Encouraging* (reminding governments of the obligations they have assumed)
- *Joint working with governments* (e.g., Wetlands International's International Waterbird Census (IWC))
- *Monitoring and assessing sites* (e.g., Important Bird Areas, Ramsar Sites) *and species* (e.g., IUCN Red List)

Operationalizing Waterbird Flyway Conservation

There are many continuing challenges facing achieving successful migratory waterbird conservation, given that many waterbird species and populations continue to be in decline (see, e.g., Wetlands International 2010). These challenges, and recommendations to address them, are summarized and provided in Boere et al. (2006) and Global Interflyway Network (2012).

One major challenge is capacity and resourcing for implementation, which for the African-Eurasian migratory waterbird region was supported through a recent major project: "Wings over Wetlands" (WOW) supported by the Global Environment Facility (GEF) and many other donors. WOW provides a good example of the

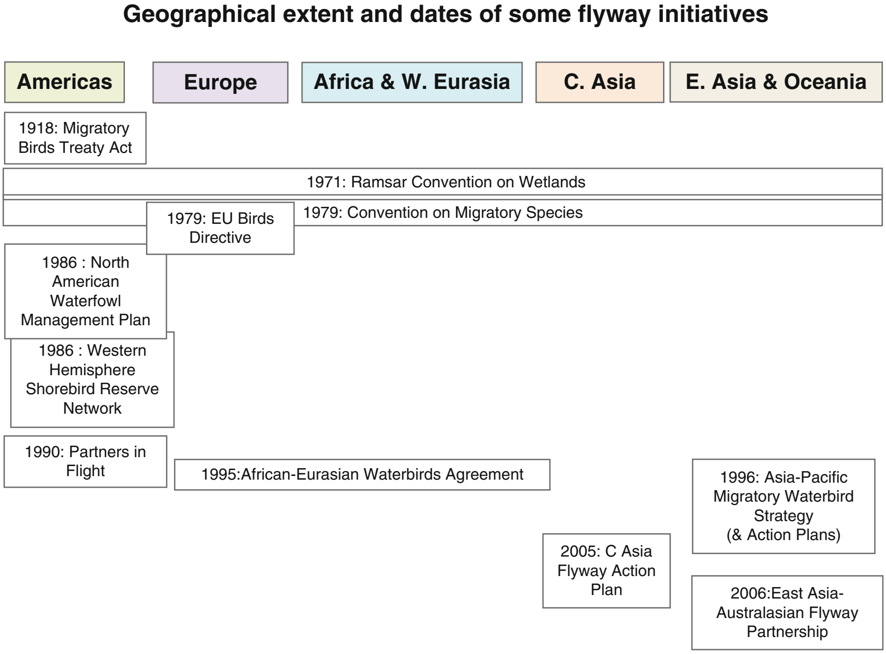

Fig. 4 The dates and geographical scope of different waterbird flyway initiatives (From: Davidson and Stroud in Global Interflyway Network (2012))

need and importance of collaborative partnerships for flyway conservation: it was a highly success collaboration between two multilateral environmental agreements (AEWA and the Ramsar Convention) and two international NGOs (BirdLife International and Wetlands International).

As well as supporting practical, on-the-ground, waterbird conservation implementation in a range of demonstration wetlands throughout the flyway, and supporting regional training centers in delivering flyway conservation training for practitioners, WOW produced two major support tools for waterbird flyway conservation. These are an online GIS-based "Critical Site Network" (CSN) tool, and a Flyways Training Kit. The approach of the CSN tool, and much of the content of the Flyways Training Kit, is highly relevant to implementing waterbird conservation on other flyways. Further information about WOW and access to these two support tools is on: http://www.wingsoverwetlands.org/.

African-Eurasian Waterbird Agreement (AEWA) and Wetland Management

61

Robert J. McInnes

Contents

Abstract

The Agreement on the Conservation of African-Eurasian Migratory Waterbirds (AEWA) is an intergovernmental treaty, which targets the conservation of migratory waterbirds and their habitats across Africa, Europe, the Middle East, Central Asia, Greenland, and the Canadian Archipelago. The agreement was developed under the framework of the Convention on Migratory Species (CMS) and is administered by the United Nations Environment Programme (UNEP). AEWA brings together countries and the wider international conservation community in an effort to establish coordinated conservation and management of migratory waterbirds throughout their entire migratory range.

Introduction

The Agreement on the Conservation of African-Eurasian Waterbird Agreement (AEWA) is an intergovernmental treaty which targets the conservation of migratory waterbirds and their habitats across Africa, Europe, the Middle East, Central Asia, Greenland, and the Canadian Archipelago. The Agreement was developed under the framework of the Convention on Migratory Species (CMS) and is administered by the United Nations Environment Programme (UNEP). AEWA brings together countries and the wider international conservation community in an effort to establish coordinated conservation and management of migratory waterbirds throughout their entire migratory range.

Species Covered by AEWA

AEWA covers 255 species of birds which are dependent on wetlands for at least part of their annual cycle. The Agreement therefore addresses many species of divers, grebes, pelicans, cormorants, herons, storks, rails, ibises, spoonbills, flamingos, ducks, swans, geese, cranes, waders, gulls, terns, tropic birds, auks, frigate birds, and even the South African penguin.

All AEWA species traverse international boundaries during their migrations and are dependent on high-quality habitats for breeding as well as a network of suitable feeding and roosting sites along their flyway. International cooperation across their entire migratory range of these wetland-dependent species is therefore essential for the conservation and management of migratory waterbird populations and the habitats on which they depend.

History of AEWA

The Convention on Migratory Species (CMS) of Wild Animals came into force in 1983, with the specific goal to provide for the conservation of migratory terrestrial, marine, and avian species throughout their range. At the first Conference of Parties (COP1) in 1988, CMS decided to prepare an Agreement for the Western Palearctic Anatidae. The Dutch government developed a draft Western Palearctic Waterfowl Agreement as part of its Western Palearctic Flyway conservation program; however, during the drafting process, the name of the Agreement was changed into the African-Eurasian Waterbird Agreement (AEWA), in order to emphasize the importance of Africa for migratory birds.

In June 1991, the final negotiation meeting on AEWA took place in The Hague, the Netherlands. The meeting adopted the Agreement by consensus and also accepted the offer from the Government of the Kingdom of the Netherlands to act as depositary and to provide an interim secretariat at its own expense until 1 January 1999. On 1 January 1996, the Dutch government established the interim secretariat, and from 15 August the same year, the Agreement became open for signature. By

November 1999, the required number of at least 14 range states, comprising at least 7 from Africa and 7 from Eurasia, had formally signed and the Agreement entered into force.

In 2000 a permanent secretariat was established and colocated with the convention secretariat in Bonn and administered by UNEP. A more detailed review of the history of AEWA is provided by Boere (2010).

Parties and Range States

Currently 73 countries and the European Union (EU) have become a contracting party to AEWA (as of 1 October 2014). A total of 39 contracting parties are from Eurasia and 33 from Africa.

Bodies of the Agreement

The Agreement has three main bodies: the Meeting of the Parties (MOP), which is the governing body of AEWA, and the Standing and Technical Committees, respectively, responsible for steering the operations between sessions of the MOP and for providing scientific advice. The UNEP/AEWA secretariat supports the parties and services the bodies of the Agreement.

Meeting of the Parties (MOP)

Established in accordance with Article VI of the Agreement, the Meeting of the Parties (MOP) is the principal decision-making body for the Agreement. The agreement secretariat convenes ordinary sessions of the MOP at intervals of not more than 3 years, unless the Meeting of the Parties decides otherwise.

The MOP is attended by representatives from contracting parties. Observers of non-party range states as well as any agencies or bodies technically qualified in relevant conservation matters or in research on migratory waterbirds can also be represented at sessions of the MOP. The MOP may make recommendations to the parties, the secretariat, the other AEWA subsidiary bodies, and stakeholders by adopting relevant resolutions and taking decisions on substantive or administrative matters.

The Standing Committee

The Standing Committee (StC) is a subsidiary body to the Agreement which provides policy and administrative guidance on behalf of the MOP to the agreement secretariat between sessions of the (MOP). Its main activities are to:

- Provide guidance on the implementation of the Agreement and management of the secretariat's programs
- Oversee the development and execution of the secretariat's budget and also all aspects of fundraising undertaken by the secretariat
- Liaise with parties and promote the flow of information to parties and vice versa
- Maintain regular contact to non-party range states and promote their accession to AEWA
- Report to the MOP on the activities that have been carried out between ordinary sessions of the MOP

The StC comprises:

- Representatives from five contracting parties, based on the principle of balanced geographical distribution (two from the Europe and Central Asia region, one from the Middle East and Northern Africa region, one from the Western and Central Africa region, and one from the Eastern and Southern Africa region)
- A representative of the host country for the next session of the meeting of the parties
- A representative from the depositary

The Technical Committee

The Technical Committee (TC) is a subsidiary body to the Agreement which has the following general functions:

- It provides scientific and technical advice and information to the MOP and, through the agreement secretariat, to parties.
- It makes recommendations to the MOP concerning the action plan, implementation of the Agreement, and further research to be carried out.
- It prepares a report on its activities for each ordinary session of the MOP.
- It carries out any other tasks referred to it by the MOP.

The TC membership comprises:

- Nine experts representing the different regions of the agreement area (Northern and Southwestern Europe, Central Europe, Eastern Europe, Southwestern Asia, Northern Africa, Central Africa, Western Africa, Eastern Africa, and Southern Africa) elected among all the parties of the region in question
- One representative appointed by each of the following organizations: the International Union for Conservation of Nature (IUCN), the Wetlands International, the International Council for Game and Wildlife Conservation (CIC)
- One thematic expert from each of the following fields: rural economics, game management, and environmental law, elected by the parties

Observers of non-party range states and the chairperson of the AEWA StC may be invited to the meetings of the TC. A maximum of four observers from specialized international intergovernmental and nongovernmental organizations can also be admitted, and in addition invited experts may be asked to contribute to specific topics.

The Secretariat

The secretariat is the Agreement's coordinating body. Its functions include:

- The organization and servicing of sessions of the MOP and meetings of the TC and the StC
- The implementation of tasks referred to it by the MOP
- The promotion and supervision of research and conservation projects
- The encouragement of exchange of information between the parties
- The liaison with international governmental and nongovernmental organizations

North American Waterfowl Management Plan (NAWMP)

62

C. Max Finlayson

Contents

Abstract
The North American Waterfowl Management Plan (NAWMP) is an international plan established in 1986 by Canda and the United States with Mexico joining later. The purpose of the partnership established by the NAWMP is to conserve and protect wetland and upland habitats and associated waterfowl populations by connecting people with nature. It was established in response to the increasingly recognized continental scale decline of wetlands and waterfowl across North America, particularly in agricultural areas. It provides a policy framework that describes the scope and goals, identifies problems facing waterfowl populations, and sets general guidelines for addressing the problems.

C. M. Finlayson et al. (eds.), *The Wetland Book*,
https://doi.org/10.1007/978-90-481-9659-3_134

Introduction

The North American Waterfowl Management Plan (NAWMP) is an international plan established in 1986 by Canada and the United States. The purpose of the partnership established by the NAWMP is to conserve and protect wetland and upland habitats and associated waterfowl populations by connecting people with nature. It was established in response to the increasingly recognized continental scale decline of wetlands and waterfowl across North America, particularly in agricultural areas (e.g., see Tiner 1984). It provides a policy framework that describes the scope and goals, identifies problems facing waterfowl populations, and sets general guidelines for addressing the problems.

Patterson (1995) described the effort to develop the NAWMP, starting in 1979 with agreement that a plan that was continental in scope was needed to resolve the ecological factors behind effective waterfowl conservation that went well beyond the capability of any single agency or country. This approach was developed as a consequence of widening recognition that traditional approaches to waterfowl conservation, encompassing regulation of hunting and protecting important and critical habitat were not successful. The private sector in particular Ducks Unlimited encouraged the Canadian and US Governments to develop a joint approach that would provide more effective conservation.

The plan contained a strategy for regaining the waterfowl population levels that were common in the 1970s and called for \$1.5 billion to be spent over 15 years on habitat conservation with \$1 billion of this being spent in Canada. Each country needed to raise funds from a variety of public and private sources. Patterson (1995) considered this funding arrangement as one of the best thing to happen to the plan as it forced those involved to market the concept and to seek funding from beyond the traditional wildlife agencies. Mexico joined in 1988 and became a signatory to the conservation action plan in 1994. Hence, the NAWMP was extended across all of North America, working at national and regional levels on waterfowl and habitat management issues.

Patterson (1995) also noted that for the NAWMP to be successful it needed to engage with the agricultural sector and address policies and practices that led to the loss and degradation of wetlands and waterfowl populations. This necessitated a focus on common solutions both nationally and locally and enabled pooled money to be used across borders (Hollis et al. 1992).

Implementation of the NAWMP

The North American Wetlands Conservation Council (Canada) has provided leadership and a national mechanism for implementation of the plan in Canada. Information on the plan and the Canadian approach to its implementation is available at http://nawmp.wetlandnetwork.ca/index.php. In the United States, the NAWMP was authorized by the North American Wetlands Conservation Act of 1989(P.L. 101–233) and is administered by the Fish and Wildlife Service, with

USDA agencies participating as appropriate. Information on the plan and the United States approach to its implementation is available atwww.fws.gov/birdhabitat/NAWMP/index.shtm. Information from these websites has been used to provide an overview of the implementation of the NAWMP.

Leadership for the NAWMP is provided by the North American Waterfowl Management Plan Committee which provides a forum for discussion of major, long-term international waterfowl issues and makes recommendations to directors of the three countries' national wildlife agencies. It responsible for updating the plan, considering new scientific information and national and international policy developments, and for identifying the need to expand or diminish activities carried out on behalf of the plan. A NAWMP Science Support Team or "NSST" was established in 2000 as a technical advisory body and consists of three national representatives appointed by the Plan Committee Co-Chairs, one technical representative from each of the joint ventures and flyway councils, representatives from working groups or subcommittees of the NSST, and ad hoc members as required. The specific objectives of the NSST are to:

1. Foster continuous improvement in the effectiveness of plan partners' actions through the establishment of iterative cycles of planning, implementing, and evaluating conservation programs at both the continental and joint venture levels.
2. Conduct large-scale studies of landscape variation and waterfowl demography.
3. Report annually to the Plan Committee and Plan partners on the status of the biological foundations of the plan, evaluation results, and their implications for future conservation activities.

The NAWMP comprises a set of guiding principles and objectives for waterfowl populations and wetland conservation, including restoration, and operated as a joint venture with support from other sectors, including NGOs, in particular Ducks Unlimited (Patterson 1995). The NGOs were seen as critical for maintaining the momentum and supporting the planning and early initiatives, including engaging with the farming communities in areas containing important habitat for waterfowl. At a governmental level, The North American Wetlands Conservation Act 1989 and the funding commitment of the Canadian Government was critical to the initial viability of the plan.

The plan has been updated on a regular basis with input from the waterfowl conservation community. The updates in 1994, 1998, and 2004 supported the goal of securing abundant waterfowl populations through science-based habitat conservation. A major revision to the plan was completed in 2012 with a renewed call to action for the waterfowl conservation community with a vision of "People conserving waterfowl and wetlands" based on adaptive management with clear goals and integrated measurable objectives for populations, habitat, and people (see documents at http://www.nawmprevision.org). It also resulted in the following three goals being agreed:

Goal 1: Maintain long-term average populations of breeding ducks [1955–2014 in traditional survey area (TSA) and 1990–2014 in eastern survey area (ESA)] and periodically, 40 million or more total breeding ducks and 2.7 million or more breeding ducks in the TSA and ESA, respectively.
Goal 2: Increase waterfowl conservation support among various constituencies to at least the levels experienced during the last two decades.
Goal 3: Conserve a habitat system with the capacity to maintain long-term average waterfowl population levels, to periodically support abundant populations, and to consistently support resource users at objective levels.

The revised plan was accompanied by an Action Plan that reflected broad input from the waterfowl management community and provided further details, guidance, and technical direction for the implementation of recommendations and actions. These Actions are expected to evolve as the waterfowl community works towards achieving the above stated conservation goals. The detailed roles of technical committees and administrative bodies in the delivery of the Action Plan are also outlined, with three recommendations being highlighted as priorities for immediate action:

1. Building support for conservation – the need to communicate the value of waterfowl and wetland conservation to the public has emerged as a top tier issue.
2. Development of new NAWMP objectives for waterfowl populations, habitat, and people – the objectives should be clear and measurable, based on the best available science and modeling, and include management actions with associated outcomes, assumptions, and uncertainties.
3. Integrated Waterfowl Management – to ensure the suite of recommendations and existing waterfowl management activities into a coherent and adaptive framework.

The success of the NAWMP depends on the strength of partnerships, called “joint ventures,” involving federal, state, provincial, tribal, and local governments, businesses, conservation organizations, and individual citizens. Joint ventures typically develop implementation plans that focus on areas of concern identified in the plan. There are 18 habitat joint ventures in the United States and 4 in Canada. Two of these have international status, one with boundaries stretching across the Canadian-United States border and one that encompasses areas of the United States and Mexico. Three species joint ventures have also been formed to address monitoring and research needs of specific species or species groups. The species joint ventures are also international in scope.

Despite the successes of the plan, there are still many challenges for waterfowl management, including urbanization and increasing demands for energy and water that influence land use decisions with direct and indirect consequences for waterfowl and other wildlife. Declining numbers of waterfowl hunters, a traditional funding source, is also of concern for maintenance of habitat management and restoration programs. The revision of the NAWMP in 2012 addressed the continuing loss of habitat, management of waterfowl populations, and engaging people who value waterfowl and wetlands.

Transboundary Wetland Management

63

Contents

Abstract

Throughout history, watercourses have offered a convenient geographical demarcation line for defining frontiers between nations. It is no surprise therefore to find numerous examples around the world of wetland systems which straddle these frontiers. Conservation, management and use of these systems thus depends heavily on transboundary cooperation. The Convention on Wetlands (Ramsar Convention) has led much of the attention to this at global level: some of the Convention's key provisions are highlighted in this chapter, along with examples of several other policy, legal and institutional mechanisms of relevance.

Introduction

Throughout history, watercourses have offered a convenient geographical demarcation line for defining frontiers between nations. It is no surprise therefore to find numerous examples around the world of wetland systems which straddle these frontiers, each in an ecological sense "belonging" to more than one country. Conservation, management, and use of these systems thus depend heavily on transboundary cooperation. (The term "transboundary" can apply to administrative boundaries within countries as well as between them; but the discussion here refers to its use in the international sense only.)

The mobility of water and migratory animals in particular extends the "ecological" logic of cooperation beyond the borders themselves to other forms of connectedness, such as hydrological catchments and international networks of sites. Further still, the services provided by wetlands (including food, tourism, and carbon storage) are traded in global markets, while flows of knowledge and financial assistance for wetland management criss-cross the world in a growing web of linkages.

The Convention on Wetlands (Ramsar Convention) [*cross-reference*] has been the pre-eminent intergovernmental framework for enabling organized attention to this at global level, and some of its key provisions are highlighted below. Several other policy, legal, or institutional mechanisms are relevant too, and examples of these are mentioned.

International Cooperation is a Fundamental "Pillar" of the Ramsar Convention

The very existence of the Ramsar Convention, as a legal agreement concluded by governments to express their shared desire to achieve common aims for wetlands, is itself a strong manifestation of international cooperation. The text of the treaty, adopted in 1971, refers to the fact that "waterfowl in their seasonal migrations may transcend frontiers and so should be regarded as an international resource" and that "the conservation of wetlands and their flora and fauna can be ensured by combining far-sighted national policies with coordinated international action."

This philosophy is translated into an obligation, accepted by all the Contracting Party governments, to "consult with each other about implementing obligations arising from the Convention especially in the case of a wetland extending over the territories of more than one Contracting Party or where a water system is shared by Contracting Parties" and to "endeavour to coordinate and support present and future policies and regulations concerning the conservation of wetlands and their flora and fauna" (Article 5, one of the so-called "three pillars" of the Convention).

The principal guidance adopted by the conference of parties to assist in implementing Article 5 (annexed to Resolution VII.19, 1999) explains that it is assumed that the requirement to consult refers to all obligations arising from the convention text; that the reference to "wetlands extending over the territories of more than one Contracting Party" refers to wetlands which cross international borders, whether Wetlands of International Importance (as defined and designated under the convention) or not; and that the second clause refers to cooperation “in areas such as shared wetland-dependent species, bilateral and multilateral assistance, trade in wetland-derived plant and animal products, and foreign investment practices”.

Resolution VII.19 calls upon Contracting Parties to give special attention to a number of areas of activity in support of Article 5, such as “identifying shared wetlands, river basins, and wetland-dependent species and supporting initiatives directed at the management of these in cooperation with other Contracting Parties and organizations”.

Shared Wetlands

Ramsar Parties are encouraged to cooperate in the management of all wetlands crossing international boundaries, including those in the coastal zone. Cooperation may take the form of data sharing, coordinated implementation and development of management plans, or formal institutional arrangements for joint oversight.

In the particular case of wetlands designated as Wetlands of International Importance or Ramsar Sites, formal joint arrangements may concern Ramsar Site designation in a coordinated way on both sides (or on all sides, if more than two countries are involved) to address the ecologically unified area in a coherent way.

To date the European region has led the way with this. Around 30 European Ramsar Parties have identified all transboundary wetland systems in their countries, and beginning with a first example in 2001, 15 areas have so far been formally notified as “Transboundary Ramsar Sites.” This title signifies a cooperative management arrangement and helps to raise awareness of the true ecological (rather than geopolitical) nature of the site: it is not a distinct legal status for the Ramsar sites involved. Regular exchanges of experience at regional level on operating these arrangements also take place. Only one non-European example exists at present, in Africa. Transboundary Ramsar Sites may consist of national components that are designated simultaneously and share the same name; or they may be designated at different times with different names: it is coherence of management that is key, not the method of labeling.

Shared River Basins

The principles described above for shared sites are also applicable at the level of river basins and coastal systems that cross international boundaries. According to the United Nations, 145 countries include territory within international basins, and 21 lie entirely within international basins. Cooperation may be necessary to achieve integrated management of the water resources (including groundwater) of an entire catchment area. There may also be situations where a wetland in one country is in a water catchment lying partly in another country, and where upstream actions may have downstream consequences on the other side of a national border. Coastal sites similarly may be affected by adjacent countries’ management of, for example, marine pollution.

Guidance under the Ramsar Convention on Integrated River Basin Management and Integrated Coastal Zone Management urges Contracting Parties to work together in addressing these situations. This may take place at a non-statutory level, with cooperation on technical matters such as monitoring and information exchange. A more formal mechanism used by many countries is the establishment of a joint management authority or commission for a specific river basin, usually with regulatory powers delegated by its member countries. In other cases, cooperation is framed by bilateral or multilateral intergovernmental legal agreements on transboundary watercourses, and there are now more than 300 such agreements in existence around the world.

Shared Species Populations

Wetland animals and plants often also need to be addressed in a transboundary context. The natural range of a species requiring special conservation measures may straddle an international boundary, and any population management actions may therefore need to be coordinated between the countries concerned. Cooperation in respect of border controls may be important in restricting the spread of invasive species or disease-carrying organisms that pose a threat to wetlands.

The most familiar case is probably that of migratory wetland species (including fish, turtles, and aquatic mammals as well as waterbirds). The ecological conservation requirements of these species typically depend on the maintenance of networks of critical wetland habitat distributed throughout their migratory range and on the limiting of any harvesting or hunting to levels that are sustainable for the population as a whole. Setting objectives at a site-by-site level is therefore not enough, and a strategic approach is essential. Many international partnerships, plans and programs now exist for the conservation of shared waterbirds and their habitats, organized according to individual defined migratory routes or “flyways.” The Ramsar Convention Parties in 2008 adopted a comprehensive decision (Resolution X.22) on promoting such flyway cooperation.

Exchange of Know-How and Financial Support

A significant aspect of Article 5 of the Ramsar Convention is its relevance to the role of international flows of development funding and other assistance. In Resolution VII.19, Parties have agreed to raise the level and effectiveness of international development assistance programs directed at the conservation and sustainable use of wetlands and also to ensure that environmental assessments and other safeguards are an integral component of all development projects that affect wetlands, including foreign investments.

Parties are also called upon to share expertise and information and provide training for people involved with wetland conservation and wise use activities. The concept of “twinning” and other forms of networking between Ramsar Sites in different Contracting Parties is encouraged as a way of promoting dialogue and sharing experience.

Ramsar Regional Initiatives

Beginning in the Mediterranean in the early 1990s, and since spreading to around 20 other areas of the world, a mechanism of international cooperation to provide support for improved implementation of the Ramsar Convention has evolved at the regional (sub-global) scale, in the shape of the convention's formal "Regional Initiatives." These are developed by groups of Contracting Parties with a common geographical focus, or in some cases with a common thematic goal, who apply for endorsement from Ramsar's governing bodies to operate as a collaborative entity within the framework of the convention. The initiatives typically comprise either a network for capacity building and cooperation or a "center" for training and capacity building. Each is governed independently but must meet strict requirements for accountability to the convention. Some have received financial assistance from the Ramsar budget, for start-up periods of up to 3 years.

Other Relevant Legal Frameworks

Ramsar is the convention particularly dedicated to wetlands; but other international agreements are also relevant, and Ramsar has formal cooperation arrangements with many of them (this can be thought of as "meta-level" international cooperation).

Reference has been made above to the numerous instruments addressing transboundary watercourses. Two of particular note are administered under the United Nations system: the 1997 UN Convention on the Law of the Non-Navigational Uses of International Watercourses and the 1992 UN Economic Commission for Europe Convention on the Protection and Use of Transboundary Watercourses and International Lakes, also known as the Helsinki Convention or the UNECE Water Convention. Although the latter was initially for European countries, it has since been amended to allow participation by any UN Member State.

In the UNECE region, more than 150 major rivers and 50 large lakes run along or straddle the border between two or more countries. Twenty European countries depend for more than 10% of their water resources on neighboring countries, and for five of these the figure is as high as 75%. The Helsinki Convention, among other things, covers ecologically sustainable management of transboundary surface waters and groundwaters, and its commitment to integrated water resources management replaces an earlier focus on localized sources of pollution and management of separate components of the ecosystem.

In the marine environment, over 140 countries are involved in 13 Regional Seas Programmes established under the UN Environment Programme, and in most cases, these are governed by a specific regional convention established for the purpose. Migratory species conservation is addressed by the Convention on Migratory

Species (CMS), with which Ramsar implements a Joint Work Plan; and the Convention on International Trade in Endangered Species (CITES) specifically combats threats from unsustainable international trade.

Future Challenges

Key future challenges include the following:

- A continuing need to identify and document the transboundary/shared wetland systems of the world
- A need to designate more qualifying wetlands as Transboundary Ramsar Sites, especially outside the European region
- An increasing need to provide financial support from developed countries and international agencies to developing countries to assist in their implementation of the conservation and wise use of wetlands
- A need to negotiate further transboundary agreements for integrated catchment-scale management of wetland resources and strengthen existing agreements, to address inter alia the increasing challenges of water availability in light of human population increases, development pressures, and the impacts of global climate change

Transboundary Ramsar Site Management: Lake Chad

64

Robert J. McInnes

Contents

Abstract

Located between latitude 6° and 24° north and longitude 8° and 24° east, Lake Chad is the fourth largest lake in Africa and represents a vast expanse of freshwater bordering the southern Sahara. The lake is located in the largest closed or endorheic basin on the African continent and covers almost 2.5 million km^2. Lake Chad supports wetlands that are vital for the livelihoods of over 30 million people living within the basin. The successful management of this area depends on transboundary cooperation among seven different countries.

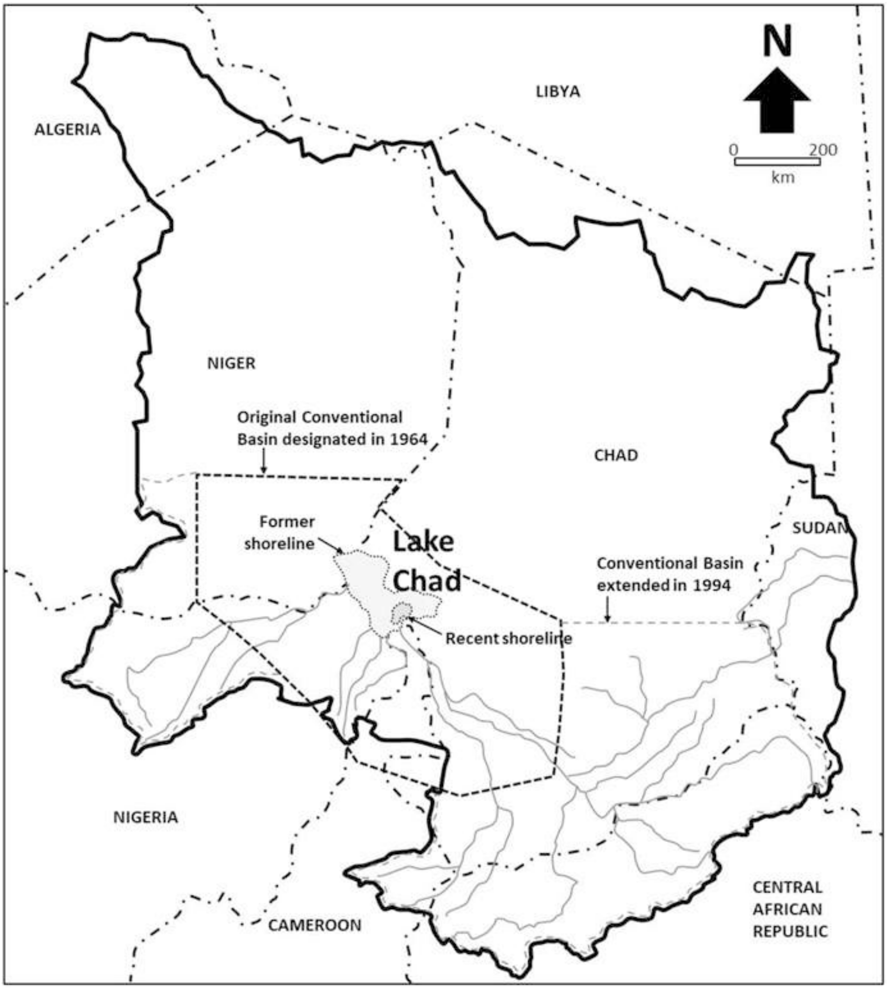

Fig. 1 The Lake Chad drainage and "conventional" basins

The overall Lake Chad basin extends into Algeria, Cameroon, the Central African Republic (CAR), Chad, Libya, Niger, Nigeria, and Sudan (Fig. 1).

The overall drainage basin comprises several subbasins. The main subbasins are those of the Lake Chad itself, Logone (between Cameroon and Chad), a tributary of the Chari (between the Central African Republic (CAR), Chad, and Sudan), Komadugu-Yobe (between Niger and Nigeria), the Borno Drainages (three rivers in Nigeria), and the Northern Diagnostic Basin which covers the largest area but makes a negligible contribution to the hydrological functioning of the Lake.

A study by IUCN (2008) described Lake Chad and its basin wetlands as a unique ecosystem in the region and a reserve of biodiversity of global significance. Like other wetlands, the ecosystem is very productive, performs a variety of functions, provides many products, and delivers various services to society. As examples, the annual contribution of the Lake Chad ecosystems to the economy has been estimated by IUCN (2008) as follows:

- Fishing: US$45.1 million
- Culture's cons season: US$26.6 million
- Breeding: US$14.7 million
- Small-scale irrigation: US$10.8 million
- Large irrigation: US$9.4 million

For millennia, periods of recharge have followed periods of drought, including a total drying out. In 1963, its most recent peak recharge, the lake surface covered approximately 25,000 km^2, but in 1985, it did not exceed 2,500 km^2 reducing to less than 2,000 km^2 in 2010. According to the United Nations' Global Resources Information Database for the environment, the extent of the lake has decreased by almost 95% between 1963 and 1998.

Over the past 30 years, the average annual rainfall within the basin has decreased by approximately 100 mm, and the evidence has been inconclusive as to whether this is a temporary climatic change or a long-term trend. Even without the presence of anthropogenic pressures, there are concerns that the hydrology of the lake could be permanently altered.

Until 1960, Lake Chad was the sixth largest lake in the world. In 1973, it covered an area of 23,000 km^2 (Grove 1996). The volume and area of the Lake decreased between the 1960s and 1990s. The chronological change in the extent of Lake Chad is clearly observed in time-lapse sequence of maps shown in Fig. 2, generated from satellite imagery, illustrating the evolution of the Lake from 1963 to 2001 (Lemoalle 1991; USGS 2001). This is summarized below:

- 1963: Open water is approximately 23,000 km^2 and each basin is connected by open water.
- 1973: The beginning of the effects of the 1972–1974 Sahelian droughts separated the northern pool from the southern by exposure of the Basin's inner ridge, the great barrier which separated an "average" Lake Chad to a "small Lake Chad" (Leblanc et al. 2011). During this period the northern pool suffered a general drying-out period and a change from an open-water lake environment to one of an unstable marshy appearance dominated by aquatic vegetation. The open water had totally dried out by 1975, and during the same period, the open-water areas of the southern pool reduced by 90% (FAO 1986 in Neiland and Béné 2004).
- 1987: The effects of both the 1972–1974 and 1982 Sahelian droughts have resulted in open water being restricted to the southern pool only.
- 1997: There was little variation over the previous decade with open water estimated to vary interannually in area between 1,500 and 2,000 km^2 plus a larger surrounding area of mixed permanent and temporary swampland of between 2,000 and 4,000 km^2.

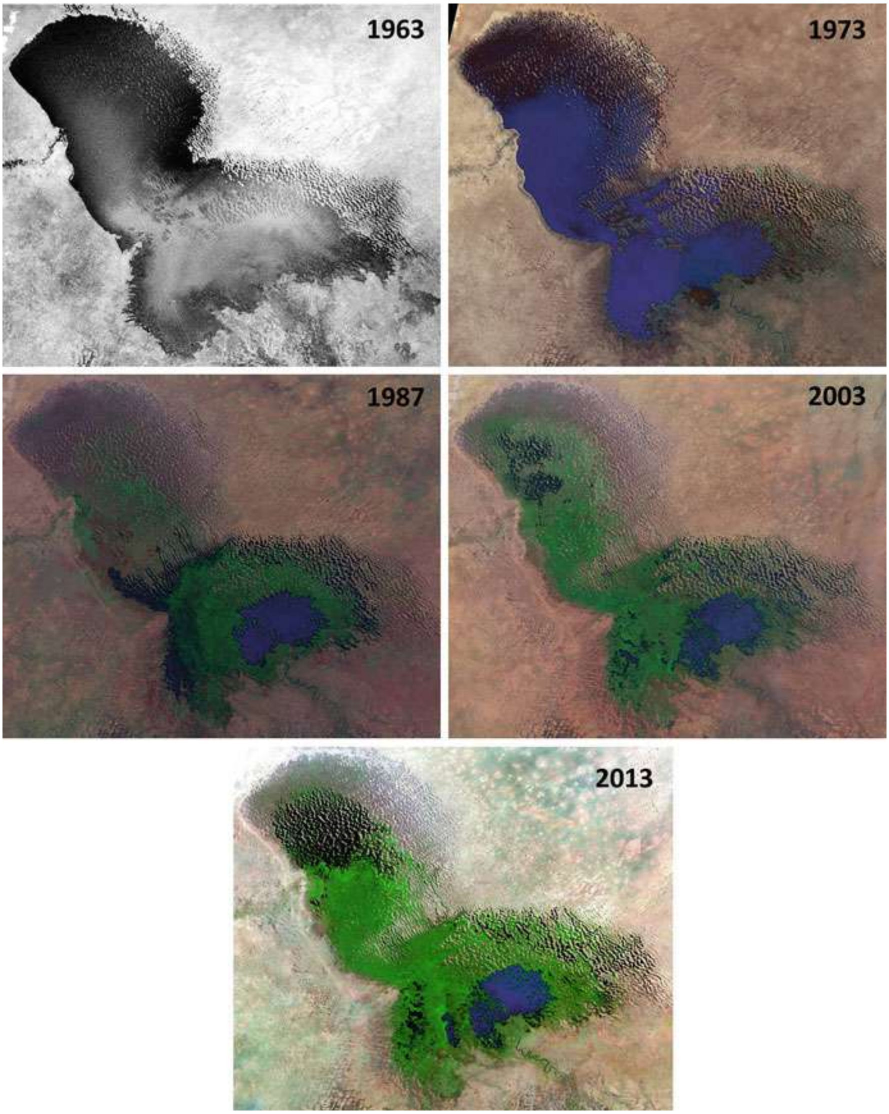

Fig. 2 Aerial images demonstrated the chronological change in the extent and distribution of surface water in Lake Chad (1987-2013) (Source of images: http://earthshots.usgs.gov/earthshots/Lake-Chad-West-Africa#ad-image-4, U.S. Geological Survey)

- 2001: The state of open-water flooding was estimated to be 1,350 km^2 with around 4,000 km^2 of swampland (Neiland and Béné 2004). The expansion in the Lake is masked by the proliferation of floating vegetation.
- 2013: The open water areas in the northern basin has continued to expand and floating vegetation covers extensive areas of surface water across the two basins.

Long-term rainfall records indicate that wetter and drier periods have been experienced in the region since the end of the nineteenth century, with the Sahelian drought being preceded by more than a decade of relatively wet years. Scientific evidence published since 2001 has indicated that river flows, rainfall, and the water levels have shown a small degree of recovery and that the lake may not be disappearing as previously feared. However, the potential implications of this information have had limited impact on the wider consciousness or decision-making processes. Similarly, attempts to model and understand the future trajectory of hydrological change are highly limited.

Given the concerns regarding the potential change to the hydrology of Lake Chad, many interventions and initiatives have been developed to mitigate the degradation of the natural resources of the basin not only to protect the livelihoods of 30 million people who depend on the Lake but also to mitigate the potential source of conflicts among the various stakeholders.

Lake Chad Basin Commission

At the regional level, the Lake Chad Basin Commission (LCBC) is the institution charged with the responsibility for sustainable development and management of water and related resources of the Lake Chad Basin. The aims of the Commission are to regulate and control the use of water and other natural resources in the basin and to initiate, promote, and coordinate natural resource development projects and research. The Commission also promotes mechanisms for settling disputes and enhancing regional cooperation (Bdliya and Bloxom 2007). The LCBC enjoys the status of an international body. The commissioners of the LCBC and the executive secretary enjoy certain diplomatic privileges and immunities accorded to officials of equivalent status of the Organization of African Unity (OAU), now the African Union (AU).

The transboundary management of the lake is the responsibility of the Lake Chad Basin Commission (LCBC), which was established in May 1964 by the Fort Lamy (now N'Djamena) Convention and Statutes by the heads of governments from four riparian countries (Chad, Niger, Nigeria, and Cameroon). The original Conventional Basin covered some 427,300 km^2. In 1994, CAR was admitted as the fifth member state bringing the size of the Conventional Basin to 966,955 km^2. Finally, in July 2000, Sudan was admitted as a member of the Convention increasing the Conventional Basin to 1,035,000 km^2 and effectively including the entire active hydrological basin.

The primary responsibilities of the LCBC are to regulate and control the utilization of water and other natural resources within the basin; to initiate, coordinate, and promote natural resource development projects and research; to examine complaints; and to promote settlement of disputes, thereby contributing to regional conflict resolution and cooperation.

Developing from work conducted by FAO and the World Bank, during the 1980s, the LCBC oversaw diagnostic studies of the Lake Chad Basin and the development of a master plan which was ratified by member states in 1994. Diagnostic studies have continued into the 2000s.

Building on the Africa Water Vision, which was endorsed at an extraordinary summit of the African Union, the LCBC has set out a vision for the Lake Chad Basin in Vision Document 2025. This states that:

> The Lake Chad Region would like to see by the year 2025 the Lake Chad – common heritage – and other wetlands maintained at sustainable levels to ensure the economic security of the freshwater ecosystem resources, sustained biodiversity and aquatic resources of the basin, the use of which should be equitable to serve the needs of the population of the basin thereby reducing the poverty level.

In June 2008 the LCBC member states of Cameroon, CAR, Chad, Niger, and Nigeria agreed to a *Strategic Action Programme* (*SAP*) *for the Lake Chad Basin* which lays down the principles of environmental management and cooperation and establishes an agenda for the delivery of the long-term vision for the sustainable development and environmental stewardship of the Lake Chad Basin.

The Fort Lamy Convention recognizes the sovereign rights of member states over the water resources in the basin while forbidding any unilateral negative exploitation of natural resources where this would impact upon the interest of other states. Additionally, the member states should consult with LCBC on the planning and implementation of projects and should refrain from undertaking activities likely to alter the water balance of the Lake or its water quality or biological resources. The LCBC, through a participatory process, now developed a Water Charter for the basin. The Charter elaborates on commitments and responsibilities of the member states toward the sustainable and equitable management of the water resources of the basin.

Future Challenges

The understanding of the dynamics of Lake Chad is fraught with complications and complexities. Lake Chad is a dynamic system driven by climatic events and modified by human impacts across the watershed. The system is not static but demonstrates variability from year to year and decade to decade.

While the hydrology has been subject to assessment for more than half a century, little attempt has been made to place the current hydrological functioning within the limits of acceptable environmental or social change or within the limits of expected future climatic variability or to fully characterize the ecosystem services provided to human society. The need to understand and manage this sensitive transboundary system will accelerate as growing human demands place more stress of the wetland environment.

The International Commission for the Protection of the Danube River (ICPDR) is a transnational body, which has been established to implement the Danube River Protection Convention. The legal basis of ICPDR is the Convention on Cooperation for the Protection and Sustainable Use of the Danube River (or more informally the Danube River Protection Convention or DRPC). This convention commits the contracting parties to join their efforts in sustainable water management, including conservation of surface and groundwater, reducing pollution, and the prevention and control of floods, accidents, and ice hazards. The convention was signed in Sofia in 1994 and came into force in October 1998.

History of Cooperation Across the Danube River Basin

Before World War II, the European Commission of the Danube, which dated back to the 1856 Treaty of Paris, comprising representatives from each of the riparian countries, was responsible for administration of the Danube River (Sommerwerk et al. 2009). Its primary goal was to ensure free navigation along the Danube for all European countries. The new political alliances manifested as a result of World War II gave rise to a new approach to management of the river basin. At a 1948 conference in Belgrade, the states from the Eastern Bloc shifted control over navigation to the exclusive control of each riparian country. A further outcome of the Belgrade conference was to bestow upon the Commission semi-legislative powers regarding navigation and inspection.

By the mid-1980s, it had become clear that issues other than navigation were gaining in importance within the Danube basin and most notably were problems regarding water quality. Recognizing the increasing degradation of water quality, in 1985 the (at the time) eight riparian states of the Danube signed the "Declaration of the Danube Countries to Cooperate on Questions Concerning the Water Management of the Danube" (or informally, the Bucharest Declaration).

The Bucharest Declaration reinforced the principle that the environmental quality of the river was intrinsically linked to the overall environment of the basin and as such committed the countries to adopt an integrated approach to water management. One of the first steps toward implementation of this integrated approach was the establishment of a transnational unified monitoring network. The changing geopolitics of the region post-1989 had implications for the Danube River Basin (Linnerooth-Bayer and Murcott 1996). Basin-wide coordination was strengthened at meetings in Sofia, Bulgaria, in September 1991. The countries and interested international institutions established an initiative to support and reinforce national actions for the restoration and protection of the Danube River. Through this initiative, the Environmental Programme for the Danube River Basin (EPDRB), the participants agreed that each riparian state would:

- Adopt the same monitoring systems for assessing environmental impacts
- Address the issue of liability for cross-border pollution
- Define rules for the protection of wetland habitats

- Define guidelines for development to conserve areas of ecological importance or aesthetic value

An interim task force was established to coordinate the efforts. Its work was supported by a Programme Coordination Unit (PCU) based in Vienna, Austria. One of the major tasks of the EPDRB was the development of the Strategic Action Plan (SAP). In order to transition from planning to implementation, the proposed SAP addressed the following concerns:

- Measures must be "concrete" and achieve results in short term.
- Major environmental threats must be addressed with realistic costed actions and constraints to problem-solving.
- The SAP should be updated regularly.
- Wide consultation during its preparation is desirable, in particular with parties who would be responsible for its implementation.

As a commitment within the SAP, during late 1993 and early 1994, the riparian countries developed the Convention on Cooperation for the Protection and Sustainable Use of the River Danube. The resultant "Danube River Protection Convention" was finally signed in Sofia on June 29, 1994. The International Commission for the Protection of the Danube River (ICPDR) became active in 1998. Since then, it has grown into one of the largest and most active international bodies of river basin management expertise in Europe dealing with not just the main Danube River but also with the whole Danube River Basin, which includes more than 300 tributaries and the groundwater resources.

How Is the Commission Managed?

The ICPDR is an international organization with the following 15 contracting parties:

- Austria
- Bosnia and Herzegovina
- Bulgaria
- Croatia
- Czech Republic
- Germany
- Hungary
- Moldova
- Montenegro
- Romania
- Slovakia
- Slovenia

- Serbia
- Ukraine
- European Union

The ICPDR meets twice a year: The Ordinary Meeting is held at the Permanent Secretariat in Vienna in December; another meeting of Heads of Delegations is held in June in the home country of the serving president. The meetings comprise of delegations of contracting parties and observer organizations. Every contracting party has one Head of Delegation representing the country. Consensus is sought for all decisions. The meetings are chaired by the ICPDR president; ICPDR presidency is passed on from one country to another in an alphabetical order every year.

In addition, much of the work of the ICPDR is done by expert groups (EGs), which comprise panels of specialists from the ICPDR contracting parties and observers, often civil servants of the relevant ministries, in some cases employees of nongovernmental organizations (NGOs) or contracted agencies. There are seven permanent expert groups and one ad hoc EG. The EGs all have terms of reference and mandates adopted by the Commission. The EGs usually meet up to three times a year.

The ICPDR is primarily not a project-implementing body, but it can take responsibility for some projects in order to achieve its core objectives. However, the ICPDR can act as an implementing entity for some project, and for others it acts as an advisor or as a facilitator for the implementation of different components through its EGs. The ICPDR also acts as a forum for the development of projects that are submitted and carried out by others (but benefiting the cooperation under the ICPDR).

The ICPDR is financed through the contributions from the contracting parties. According to the DRPC, the contracting parties (except for the EU) shall contribute an equal share, unless unanimously decided otherwise by the ICPDR. Some exceptions have been applied for transitional periods. The total annual budget of the ICPDR is in the region of one million Euros. Much of the ICPDR's work is undertaken directly by member countries, and as such these are considered in-kind contributions and are not shown in the ICPDR budget.

By acceding to the convention, contracting parties commit under international law to specific actions and to uphold certain principles. In past conflicts, the ICPDR contributed to the harmonization of efforts by providing a forum for discussion. The president or the staff at the permanent secretariat can initiate dialogue on specific issues and contribute to building consensus among contracting parties. The convention also provides a more formal dispute settlement mechanism, but in practice this has not been needed so far, as the countries concerned have achieved consensus on issues of conflict through dialogue and discussion.

In 2000, the contracting parties nominated the ICPDR as the platform for the implementation of all transboundary aspects of the European Union (EU) Water Framework Directive (WFD). The work for the successful implementation of the EU WFD is therefore high on the political agenda of the countries of the Danube River Basin District. In 2007, the ICPDR also took responsibility for coordinating the implementation of the EU Floods Directive in the Danube River Basin.

Table 1 Basic information on the countries in the Danube River Basin (DRB) (data from Danube Basin Analysis, 2005)

The Danube River Basin

The Danube River Basin covers a total area of 801,463 km^2 and is the second largest watershed in Europe. The Danube River stretches 2,780 km from Germany's Black Forest to the Danube Delta in the Black Sea. Characteristically, the basin is divided into three areas: the upper, middle, and lower basins. The upper basin extends from the source of the Danube in Germany to Bratislava, Slovakia. The middle basin is the largest of the three areas, extending to the dams of the Iron Gate gorge on the border between Serbia and Romania. The lowlands, plateaus and mountains of Romania and Bulgaria form the lower basin. Finally, the river divides into the three main branches of the Danube Delta, which covers an area of about 6,750 km^2, before entering the Black Sea.

The Danube River flows through 19 countries and is a truly transboundary, international river system. Table 1 provides further information on the countries of the Danube River Basin.

Future Challenges

The transboundary nature of the Danube River Basin management is challenging due to a lack of on-site expert knowledge, high administrative and socioeconomic complexity, the need to balance various stakeholder interests, and difficulties enforcing international and national law. Therefore, in the future, the need for an efficient "science–policy interface" is vital for the successful development and implementation of ambitions of the ICPDR (Sommerwerk et al. 2010). The various human activities continue to place environmental pressures on the Danube and its network of tributaries. Industry, agriculture, hydropower, and tourism are all economically important and depend on the Danube as a resource, yet at the same time they also threaten river ecosystems. The ICPDR continues to seek to address a range of issues and challenges through collective working and the implementation of best practice in transnational river basin management.

Indus Waters Treaty

66

Nick C. Davidson

Contents

Abstract

The Indus River is among the longest rivers in Asia and the transboundary Indus River Basin is one of the largest in the region. Rising in the Tibetan Plateau of the Himalayas, the Indus flows through Afghanistan, China, India, and Pakistan, discharging through the Indus Delta into the Arabian Sea near Karachi. The largest areas of the Basin lie in Pakistan and India. The basin faces severe water stress. Increasing conflict in the 1950s over sharing the Basin's water s between India and Pakistan led to the two countries signing the Indus Waters Treaty in 1960. The Treaty is recognized as one of the most successful transboundary water-sharing mechanisms in the world.

the Himalayas, the Indus flows through Afghanistan, China, India, and Pakistan, discharging through the Indus Delta into the Arabian Sea near Karachi (Fig. 1). The largest areas of the Basin lie in Pakistan (520,000 km^2; 65% of Pakistan's land area) and India (440,000 km^2; 14% of India's land area) (FAO 2011).

The lower reaches of the Basin are densely populated, and up to 300 million people have been estimated to live in the Basin, many of whom depend on the river and its resources. The water resources of the Indus are vital for agriculture and food production in Pakistan. Water infrastructure developments in the twentieth century have created an extensive network of dams, reservoirs, and irrigation canals which now deliver water to about 110,000 km^2 of irrigated agricultural land – the largest irrigated area of any river basin (FAO 2011).

However, the Indus Basin has been recognized as facing increasingly severe water stress. Wong et al. (2007) ranked the Indus among the world's top ten rivers at risk. The highest risk comes from climate change since the river flow largely

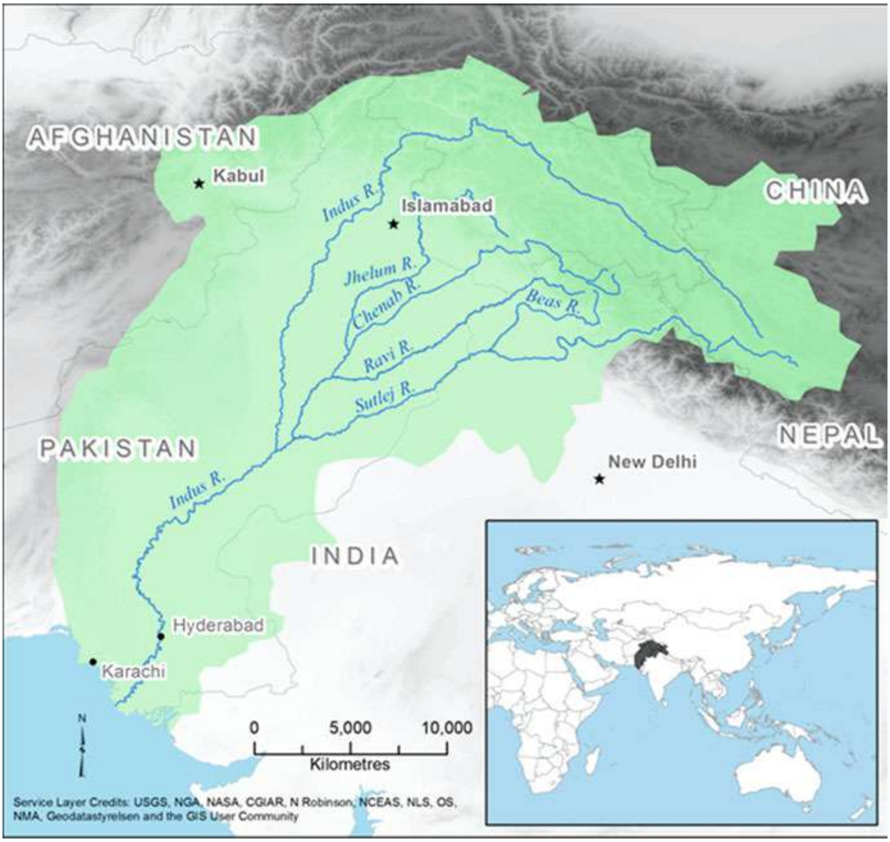

Fig. 1 Location of the Indus River Basin (© Spatial Data Analysis Network, Charles Sturt University)

comes from glacial meltwater, but also with water abstraction, agricultural pollution, and water infrastructure, including dam construction, contributing to the pressure on the river system. Similarly, the World Resources Institute (Gassert et al. 2013) assessed the Indus River Basin as having an extremely high “baseline water stress” (the ratio of total annual water withdrawals to total available renewable water supply) and with a stress score of 4.3 out of 5.0, the sixth highest risk score among the world’s major river basins.

The Indus Waters Treaty

Following the partition of the British Indian Empire in 1947, which meant that the upper tributaries of the Indus were then in India with the downstream river in Pakistan, there were increasing concerns and conflict during the 1950s over the sharing of the Indus’ waters between the two countries. There was an initial, interim agreement on allocations of Indus water – the Inter-Dominion Agreement of 4 May 1948 (http://www.internationalwaterlaw.org/documents/regionaldocs/punjab-canal.html) – through which India would release water downstream to Pakistan in return for annual payments by Pakistan. Negotiations between India and Pakistan for a more permanent agreement then stalled (World Bank undated).

Interventions by the International Bank for Reconstruction and Development (now the World Bank) led to the resumption of negotiations, on both technical and political aspects of such an agreement, and eventually led to the signing by the Indian prime minister and Pakistan president in 1960 of the Indus Waters Treaty on the sharing by the two countries of Indus water (World Bank undated). This agreement has stood the test of time and is recognized as one of the more successful transboundary water-sharing mechanisms in the world.

Despite its title, the treaty focuses on the partitioning between India and Pakistan on use of the tributary rivers of the Indus, rather than the sharing of Indus water per se. Under the treaty, the eastern rivers (Ravi, Beas, and Sutlej) are allocated to exclusive use by India, and the western rivers (Jhelum, Chenab, and Indus) allocated to exclusive use by Pakistan. An initial transition period of 10 years was agreed for use of water from the eastern rivers, during which India was required to supply water to Pakistan, pending Pakistan’s completion of canal infrastructure for the western rivers, and during which Pakistan received a one-off financial compensation payment for the loss of access to water from the eastern rivers. The full text of the treaty is available on: http://siteresources.worldbank.org/INTSOUTHASIA/Resources/223497-1105737253588/IndusWatersTreaty1960.pdf.

The treaty established a Permanent Indus Commission, with a commissioner appointed from each of India and Pakistan, and through which the agreed exchange of data and cooperation is facilitated. The commission provides the mechanisms for consultation and conflict resolution concerning the Indus. Under the treaty, the commission meets to discuss potential disputes and to facilitate cooperation on any future development of the water infrastructure of the Indus Basin. Each party (India, Pakistan) to the treaty must notify the other of any water engineering work plans which could affect the other party. When there is disagreement over such plans, the commission can bring in an independent expert to mediate and arbitrate on the issue.

Despite the successes of the Indus Rivers Treaty over the past 45 years, recent concerns have been expressed by Pakistan over the impact on downstream water resources of dam construction in the Indian portion of the Basin, and it is recognized that the treaty does not yet adequately address issues of the impacts of the changing climate on water availability in the Basin; this issue is recognized by Wong et al. (2007) as the major pressure on the Basin. A more extreme and volatile monsoon season, which led to devastating Indus Basin floods in 2010 and 2011, has also been attributed to the changing climate.

Mekong River Basin Regional Legal Framework

67

Huynh Tien Dung

Contents

Abstract

The Mekong River is a transboundary river in Southeast Asia draining a basin covering approximately 800,000 km^2. At an estimated length of 4,350 km, it is the world's 12th longest river and the 7th longest in Asia. The river rises on the Tibetan Plateau and runs through China's Yunnan province, Myanmar, Lao People's Democratic Republic (PDR), Thailand, Cambodia, and Vietnam where it discharges into the South China Sea. The origins of transnational and transboundary management of the main channel and its tributaries date from the late 1950s, culminating in 1995 with the signing of the Mekong Agreement by Thailand, Lao PDR, Vietnam, and Cambodia. The agreement codified principles of regional cooperation and established the Mekong River Commission (MRC). Under the agreement, MRC member countries agree to cooperate in all fields of sustainable development and in the utilization, management, and conservation of water and related resources in the Mekong River Basin. The MRC has a three-tiered institutional structure comprising a Ministerial Council, a Joint Committee, and a Secretariat.

Introduction

The Mekong River is a transboundary river in Southeast Asia draining a basin covering approximately 800,000 km^2. At an estimated length of 4,350 km, it is the world's 12th-longest river and the 7th longest in Asia (Mekong River Commission 2003). The river rises on the Tibetan Plateau and runs through China's Yunnan province, Myanmar, Lao People's Democratic Republic (PDR), Thailand, Cambodia, and Vietnam where it discharges into the South China Sea. The basin is characteristically divided into the Lower and Upper Basins. The Upper Basin comprises approximately 24% of the total basin area and contributes 15–20% of the water that flows into the Mekong River. The tributary river systems in the Upper Basin are small; however this changes as the floodplain becomes wider and the tributaries drain larger subbasins in the Lower Basin. The Mekong drainage network is extremely complex, and across the entire basin, its management affects the lives of approximately 60 million people (Fig. 1).

A Brief History of Transboundary Management

Going back to the 1950s, the historic governance of the Mekong has been dominated by the desire to collect a variety of hydrologic data in order to manage the Mekong into a "working" river (Sneddon and Fox 2006). Three principal goals were pursued in the 1950s, namely, the generation of hydroelectricity to develop industrial development, the storage of water in order to facilitate the expansion of irrigated agriculture, and the control of annual flood risks.

The origin of the transnational and transboundary management of the main channel and its tributaries can be traced to the late 1950s. The Committee for the Coordination of Investigations in the Lower Mekong Basin, or "Mekong Committee," was created in 1957 under the guidance of the United Nations Development Programme (UNDP). The Committee's 1957 statute mandated that it "promote, coordinate, supervise, and control water resource development projects in the lower Mekong basin." Following its inception, and over the next 15 years or so, the Mekong Committee established a network for the collection of hydrologic data. The primary use of these data was to assess the feasibility of constructing large hydroelectric generating dams on the main river and the overseeing of tributary projects within the national territories of the Lower Basin's states (Lao PDR, Thailand, Cambodia, and Vietnam).

The Mekong Committee continued to negotiate over transnational water management issues throughout the period of the Vietnam-America war, during which time South Vietnam and Lao PDR maintained a generally cooperative relationship with Thailand. However, the war effectively placed wider development of initiatives on hold, and many of the planned projects were never put into effect.

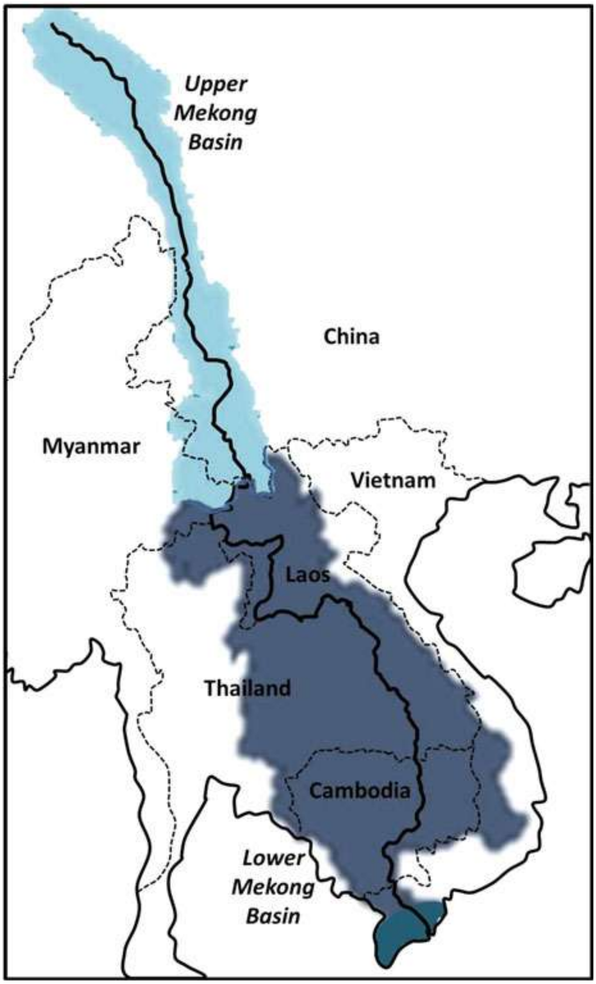

Fig. 1 The Mekong River Basin

In 1975, under the auspices of the Mekong Committee, the “Joint Declaration of Principles for the Utilization of the Waters of the Lower Mekong Basin” was signed. This Joint Declaration stressed the “resources of common interest” and effectively gave the riparian states a veto power over plans by other nations to divert water from the main river. However, implementation of the 1975 Declaration was impeded by ongoing conflict and political reform within the riparian states. Vietnam, Cambodia, and Lao PDR all underwent changes in political regime following the end of the Vietnam-America war. As a result of the prevailing geopolitics in the Basin, the Mekong Committee failed to meet in 1976 and 1977, and it appeared that the initiative would fail.

However, in 1978, Thailand, Lao PDR, and Vietnam established an interim body (called the Interim Mekong Committee) to encourage and facilitate the continuation of dialogue. Cambodia, which by now was under the rule of the Khmer Rouge, failed to participate in the Interim Committee, thus limiting the capacity of the committee to fulfill planning and management objectives at a basin-wide scale.

Through the Interim Mekong Committee, partial collaboration continued until 1991 when Cambodia resumed negotiations with the other Lower Basin countries. However, difficulties were encountered in reaching agreement on a draft Mekong Committee Declaration. These difficulties were primarily the result of a disagreement between Vietnam and Thailand over the diversion of water by the upstream state as part of the planned Khong-Chi-Mun interbasin transfer project in Northeast Thailand. Thailand demanded a review of the 1975 Joint Declaration, and the principles of which had guided cooperation in the Interim Committee to date.

In the early 1990s, the United Nations Development Programme (UNDP) intervened, establishing a working group to investigate future collaboration in the Lower Basin. Working group meetings involving the riparian countries continued through 1993 and 1994. The outcome of these meetings was the draft *Agreement on the Cooperation for the Sustainable Development of the Mekong River Basin* (the Mekong Agreement).

The 1995 Mekong Agreement and the Mekong River Commission

On 5 April 1995, the Mekong Agreement was signed by Thailand, Lao PDR, Vietnam, and Cambodia. The Agreement codified principles of regional cooperation and established the Mekong River Commission (MRC) (http://www.mrcmekong.org/). Under the Agreement, MRC member countries agree to cooperate in all fields of sustainable development and in the utilization, management, and conservation of water and related resources in the Mekong River Basin, for example, navigation, flood control, fisheries, agriculture, hydropower, and environmental protection. This approach to transboundary management has been lauded as the most progressive of institutional frameworks for the governance of an international watercourse but also encounters many challenges.

Under the auspices of the Mekong Agreement, the MRC has a three-tiered institutional structure comprising a Ministerial Council, a Joint Committee, and a Secretariat. The Council is the highest body within the organization and is responsible for overseeing MRC activities and directing MRC policies. The Joint Committee is responsible for implementing Council initiatives and supervising the activities of the Secretariat.

The Secretariat, which is based in Vientiane, Lao PDR, is responsible for the day-to-day administration of MRC affairs and for the development and implementation of a variety of programs. In order to assure neutrality, the Chief Executive Officer of the Secretariat is a citizen of a non-riparian state. Representative parity for each riparian state is practiced within the secretariat in order to employ equal numbers of staff from each member state. A key MRC policy, which enables ongoing capacity building in river basin management, is to limit staff tenure to a maximum of 6 years.

Future Challenges

While many elements of the transboundary management of the Mekong River have been successful, the future is not without challenges. At the Mekong Summit in 2010, the prime ministers from the four MRC countries decreed that the organization would need to move from a position of almost total dependency on external funding to a position of self-financing by 2030. A suggestion was to move toward decentralization and a greater level of national implementation (MRC 2012). Challenges also remain regarding the hydropolitics of environmental conflicts. It has been argued that the major challenges facing the transboundary management of the Mekong River are not necessarily among riparian states, but rather they will involve conflicts between state agents (such as dam-building agencies, power generation departments, and irrigation organizations) and non-state actors (such as civil society groups and local communities) over specific interventions and alterations of the river environment (Sneddon and Fox 2006).

Murray-Darling Basin: Conservation and Law

68

Jamie Pittock

Contents

Abstract

Better wetland conservation law can be informed by lessons from Australia's Murray–Darling Basin. The legal character of water entitlements is critical for ensuring that water is available to adequately sustain wetlands. Better management has been informed by national harmonization of water data collection and providing public access to this information. An independent statutory manager of environmental water in the Federal Government has ensured that environmental water is protected are used to conserve wetlands. Domestic law has been considerably strengthened by drawing on international treaties, especially the Ramsar Convention on Wetlands. Overlapping roles of federal and state governments have hindered some conservation initiatives but have also ensured some level of wetland conservation continues at one level of government when the other level of government does not do so. As direct government action has become more financially and politically constrained, businesses, community organizations, and Indigenous peoples have been enabled to play greater roles in conservation of

Introduction

Conservation of wetlands in the Murray-Darling Basin has been advanced by the evolution of environmental and water laws that have been increasingly influenced by international environmental agreements. The basin occupies a seventh of the Australian continent, nearly a tenth of this area; some 5.7 million hectares are regarded as wetlands (Kingsford et al. 2004).

The basin largely lies in the Mediterranean temperate zone and is especially prone to water scarcity, extreme events, and climate change, requiring the development of institutions for managing great hydrological variability that may hold lessons for other areas of the world (Grafton et al. 2012). As Australia has a federal system of government, lessons for wetlands and river basin governance in the basin are likely to be particularly applicable in the 28 federations globally (Garrick et al. 2013). In this chapter the history of water-related laws is outlined before focusing on recent wetland conservation initiatives, including the influence of international agreements.

Indigenous Laws and Institutions

Prior to European occupation, the wetlands of the basin were focal points in the territories and livelihoods of several dozen Aboriginal nations. One example is the Willandra Lakes World Heritage Area that is shared by three Indigenous nations and holds some of the oldest remains of human occupation of Australia (Australian Government 2002). Institutions existed that governed the extensive and sustainable use of wetland resources that are indicated by such sites as a canal to enable eel migration across catchment and permanent fish trap infrastructure (Bandler 1995; Lintermans 2004).

While the Indigenous nations were substantially dispossessed in the basin, the 1992 decision to recognize that native title remains where unbroken cultural and economic use of lands can be demonstrated, and the increasing return to and purchase of land by Aboriginal communities means that a modest but growing portion of the basin's wetlands is under Indigenous management (as detailed below). In 2004 the federal and state governments agreed in the National Water Initiative to recognize the Indigenous people's rights to water for cultural and economic purposes (Commonwealth of Australia et al. 2004; Jackson and Morrison 2007). Although a First People's Water Engagement Council was formed to advise on implementation (First People's Water Engagement Council 2012), the definitions of cultural water needs and mechanisms to give these effects remain contested (Weir 2011).

Early European Water Laws and Institutions

The early European occupiers of Australia quickly realized that the extreme hydrological variability of the basin required new kinds of water laws. Deliberately rejecting the Western United States prior appropriation model, the Australian colonies – later states – largely adopted water use entitlement that is an annual share of the available resource (Connell 2007). When Australia federated, the management of natural resources was largely left as the responsibilities of the states, despite an ambiguous clause in the constitution preventing the Commonwealth Government from unreasonably abridging the rights of the states to the conservation (utilization) of water. The debates over sustainable management of the River Murray's waters in the federation conventions continue to this day (Connell 2007).

In 1915 the three lower basin states and Commonwealth Government formed a River Murray Commission to undertake the development of infrastructure for shipping – even then largely superseded – and irrigated agriculture. Decades later the increasing degradation of the basin's rivers and other wetlands due to water diversions was expressed through rising salinity levels, and in 1991, a 2,000 km long, poisonous cyanobacteria bloom (Bowling and Baker 1996). This was the catalyst for the Murray-Darling Basin Agreement, formation of the Basin Commission and subsidiary natural resource management programs, institutions that were based on consensus between all six states, territory, and federal governments (Connell 2007). However these initiatives failed to stem the ecological decline of the basin's wetlands, and severe drought prompted further reform in 2007–2008 (Grafton et al. 2014).

Wetland Conservation Laws and Institutions

Following the 1983 dispute over the Tasmanian state government's plans to dam the Franklin River, the federal government began using its constitutional powers to legislate to implement international agreements and to regulate trading corporations to conserve the environment (Fisher 2003). While Australia ratified the 1971 Ramsar Convention on Wetlands and nominated many sites in the basin to the Register of Wetlands of International Importance, initially they had no effective protection in domestic law. Similarly a number of migratory species agreements signaled intent but not domestic legal protection. The 1992 Convention on Biological Diversity was translated into laws at the federal level and a number of states that enabled the evaluation and listing of threatened species and also ecological communities, which then required the preparation of recovery plans (State of the Environment Committee 2011). Many aquatic species and some ecological communities have been listed for legal protection and conservation. Threatening processes can also be nominated and listed under federal law, requiring the protection of threat abatement plans, although this mechanism has been ineffectual to date.

More effective has been the National Reserve System and Indigenous Protected Areas programs (Ross et al. 2009; State of the Environment Committee 2011), which from the late 1990s saw large areas of wetlands acquired and designated for conservation, for instance, in the Paroo River catchment. The National Reserve System program provided federal government matching funding to state government agencies and nongovernment conservation land trust groups to acquire lands containing underrepresented ecosystems for conservation reserves. For instance, Bush Heritage Australia acquired the 14,400 ha property Naree Station to conserve significant wetlands (BHA 2014).

In 1999 the Commonwealth Environment Protection and Biodiversity Conservation Act (EPBC Act) was adopted, which now names nine “matters of national environmental significance” where the federal government requires proponents of “new actions” that may significantly impact on one or more of these matters to undergo environmental assessment and approval (Australian Government 1999). This ensures a more objective assessment of proposed actions compared with those of the pro-development state governments. The EPBC Act codified many aspects of the Ramsar Convention on Wetlands in domestic law. The requirement for environmental impact assessment of new developments extends beyond the Ramsar site boundary to include actions that may significantly impact upon its ecological character, such as any new, upstream water diversions. These legal ramifications prompted the Commonwealth Government to fund proper mapping of Ramsar site boundaries, defining the ecological character of each site, as well as preparing management plans. Despite at least one outdated critique (Farrier and Tucker 2000; Blasco 2001), Ramsar listing has resulted in a renewed focus on providing modest environmental flows to the designated wetlands in the basin, including in the Basin Plan (Gardner 2012).

However, the EPBC Act also generated risk-adverse responses from the governments that has diminished potential wetland conservation activities (Pittock et al. 2010). Concern over federal government regulation of Ramsar sites has seen state governments designate fewer wetlands, exhibiting a misplaced fear since migratory and threatened species, among other matters, already enable federal regulation of new developments in most significant wetlands in Australia. After early conflicts with the states and nongovernment litigators, the Commonwealth Government administrators have also ceased to designate new Ramsar sites unless a proposal has a state government agreement, a surveyed site boundary, an ecological character description, a management plan, and an environmental flow agreement (SEWPAC 2012). In the absence of strong public support for site conservation, these exhaustive bureaucratic requirements have stalled new wetland conservation measures even though the Commonwealth Government could choose to override any state government opposition.

The EPBC Act did not legislate to implement a number of other national obligations under the Ramsar Convention, for example, establishment of a national wetlands advisory committee, nor an indicative list of sites that should be considered for Ramsar designation. Despite the EPBC and Water acts, the ecological character of a great many of the listed wetlands continues to decline (Pittock et al. 2010). While the Australian Government has reported a few of these cases to the Ramsar Secretariat as required by Article 3.2, many have not been reported (Pittock et al. 2010; Ramsar 2009). The Australian Government has also unilaterally decided not to report changes in ecological character due to climate change while at the same time funding an extensive program of "environmental works and measures" – major infrastructure intended to conserve wetland biodiversity with less water that has been questioned by academics (DEWHA 2009; Pittock et al. 2012).

The Water Act and the Basin Plan

In 2007–2008 at the peak of the Millennium Drought, the Commonwealth Government gained grudging consent from the state governments for it to regulate water management in the basin. The resulting Water Act requires the Commonwealth Government to set "sustainable diversion limits" based on best available science in a Basin Plan that is to be revised at least every 10 years (Commonwealth of Australia 2008). In large part the Water Act derives its constitutional mandate from implementation of the Ramsar Convention, migratory species agreements, and the Convention on Biological Diversity (Pittock et al. 2010). This quickly sparked a political debate as to whether the Water Act required environmental sustainability first and then optimization of economic and social welfare (a reasonable reading of the law) or whether the three objectives should be balanced, as interpreted by subsequent governments. Obtaining the consent of all the state governments to the Water Act has required the Commonwealth Government to grant more than ten billion Australian dollars, often spent in ways that economists regard as poorly targeted (Grafton 2011), as well as delaying full implementation of the Basin Plan to 2019 (Pittock 2013).

The new Murray-Darling Basin Authority has undertaken an analysis of water required to conserve wetlands throughout the system, and while it is proposed to reallocate up to 27% of consumptive water to wetland conservation in the Basin Plan (Commonwealth of Australia 2012), it is questionable where this is a sufficient volume of water. It is notable that a number of key wetland conservation issues are yet to be resolved, including the representativeness of the wetlands being watered, allocation of water to wetlands in dry years under existing state government operating rules and adaptation to climate change (Grafton et al. 2014; Pittock 2013).

The Water Act has other benefits for wetland conservation, including better data and environmental water management. Different state water accounting systems have been harmonized under the national Bureau of Meteorology, providing comparable data for better management (Commonwealth of Australia 2008; BoM and ABS 2011). The Water Act also establishes a Commonwealth Environmental Water

Holder (CEWH) to hold and manage the water entitlements acquired for the environment by the federal government through purchase and funding water efficiency savings (Connell 2011). In the past, environmental ("rule-based") water was that left after consumptive entitlements had been allocated and this diminished significantly in dry years. With the purchase of entitlements, the water held by the CEWH ("water entitlements ") – which may eventually amount to a quarter of the environmental water – has the same legal characteristics as the water entitlements held by farmers and is less easily politically manipulated.

Increasing Influence of Nongovernment Organizations

Budget cuts and the greater politicization of water management and wetland conservation have seen governments designate fewer wetland reserves in the past decade. Instead there has been a rise in involvement of business, environmental, and Indigenous organizations in wetland governance. Businesses wanting to demonstrate their sustainability practices have undertaken some innovative wetland restoration and conservation programs, including the major wineries Banrock Station and Chateau Tahbilk. After a protracted process of gaining government concurrence, five floodplain graziers and Banrock Station had portions of their wetlands designated as Ramsar sites, partly in an effort to pressure the governments to restore adequate environmental flows (NSW Ramsar Managers Network 2010; DoE 2011).

Nongovernment environmental organizations are moving beyond acquisition of land to become involved in trading, ownership, and management of water entitlements in order to restore wetland health. The Murray Wetlands Working Group is one example of a community organization selling un-needed water and acquiring water when required, often using the irrigation canal system to water wetlands (MWWG 2014). Numerous legal and operational constraints to using water for wetlands rather than irrigated agriculture are gradually being overcome.

Indigenous communities are also reclaiming their lands as these two New South Wales examples illustrate. The property Toogimbie was acquired by the Indigenous Land Corporation (a quasi-government agency that acquires land for dispossessed communities) and returned to the Nari Nari Tribal Council. These traditional owners have designated the floodplain of the Murrumbidgee River as a 4,600 ha Indigenous protected area (DoE 2013). In 2010 the New South Wales Government accepted advice from its Natural Resources Commission for around 20,000 ha of the Werai floodplain forests and Taroo lake to be owned and managed by their traditional owners as Indigenous protected areas (NRC 2009).

Conclusions

The evolution of wetland conservation law in the Murray-Darling Basin holds a number of lessons for other places. Allocating water entitlements as a share of the available resource is key to ensuring that some water is available to wetlands in dry years. Harmonizing data collection and public access is vital for providing information needed for better management. The establishment of a separate, statutory manager of environmental water ensures that this resource is deployed to best conserve wetlands. Bringing into domestic law provisions from international agreements like the Ramsar Convention can be used to increase wetland conservation measures. Overlapping powers between different levels of government (in this case, federal and state governments) may delay action but can also ensure additional consideration of wetland conservation where there is a pro-development government. Finally, enabling businesses, community organizations, and Indigenous peoples to play roles in wetland governance achieves more than governments will alone, enables innovation, and creates new constituencies for wetland conservation.

The Okavango Delta Legal Framework

69

Lars Ramberg

Contents

Abstract

The political and legal framework regulating the management of the Okavango Delta in Northern Botswana, its water, land, and natural resources is extremely complex. On a local level this is caused by frictions among traditional users, initially hunter-gatherers and latterly agriculturalists, professional hunters, and tourist operators. These uses are managed by systems of wildlife management areas, game reserves, and national parks with a trend in time away from informal local management to national governance. The Delta receives all its water, apart from direct rainfall, from the upstream riparian countries of Angola and Namibia. To manage this has resulted in the formation of a joint management structure, the OKACOM. In particular, the biological productivity, biodiversity, and beauty of the Delta makes it unique, and it has therefore been gazetted both a "Wetland of International Importance" under the Ramsar Convention and a "World Heritage Site" under the UNESCO. However, the uniqueness of the Delta is the product of the inflowing water: the quantity water, chemistry, and sediment transport. None of the protective measures address this fact, and as the pressure from the two

upstream countries to use the river water for irrigation, diversion, and hydroelectric power production now is escalating, the integrity of the Delta is under serious threat. An improved agreement between the three riparian states is needed to address the standards of the inflowing river water, maintenance of water quantity and hydro-period, nutrients and bicarbonate concentration, as well as sediment transport. This will in turn require agreements about developments in the whole drainage basin. Such ambitions are reflected in the joint OKACOM documents, while the national plans on the contrary express the urgent ambitions to enter into river water exploitations. The risk that such actions will result in the destruction of the Delta environments is considered to be very high.

History

The Okavango Delta has been maintained in a fairly pristine state mainly due to deterrent factors. The population density in the whole drainage basin (Ramberg 2014) is very low due to low agricultural potential, a result of nutrient-poor Kalahari sands and low erratic rainfalls. In addition, all inflowing water to the Delta emanates from Angola that until 1975 was ruled as a sleepy colony by Portugal. Added to this, there have been several wars and conflicts. After independence in 1975, Angola was thrown into a civil war that, to a large extent, took place in the river basin. This conflict ceased in 2001. Namibia, through which the middle part of the river flows (Fig. 1), was a colony under South Africa until 1990. Up until 1990 a liberation war took place which effectively transformed northern Namibia into a war zone. Under such unruly conditions, no economic development initiatives could be taken (Wolski et al. 2010).

The Delta where the Okavango River ends lies in the northwestern part of Botswana, a very remote and inaccessible area in the middle of the Kalahari. Livestock rearing which is the main economic activity was not possible in the Delta due to wildlife-vectored diseases, in particular foot-and-mouth, and the tsetse fly which carries sleeping sickness to both livestock and humans. The fly was not erased until 2002.

With the independence of Botswana in 1964, a number of water development projects – such as irrigation and channeling of water usually financed by foreign aid – were initiated in the period 1960–1990. All of these initiatives failed due to a lack of knowledge of the nature of the Delta and/or lack of understanding of social and cultural factors.

Due to this cluster of deterring factors, there has been little need for any conservation measures until the last two to three decades. Need has arisen due to

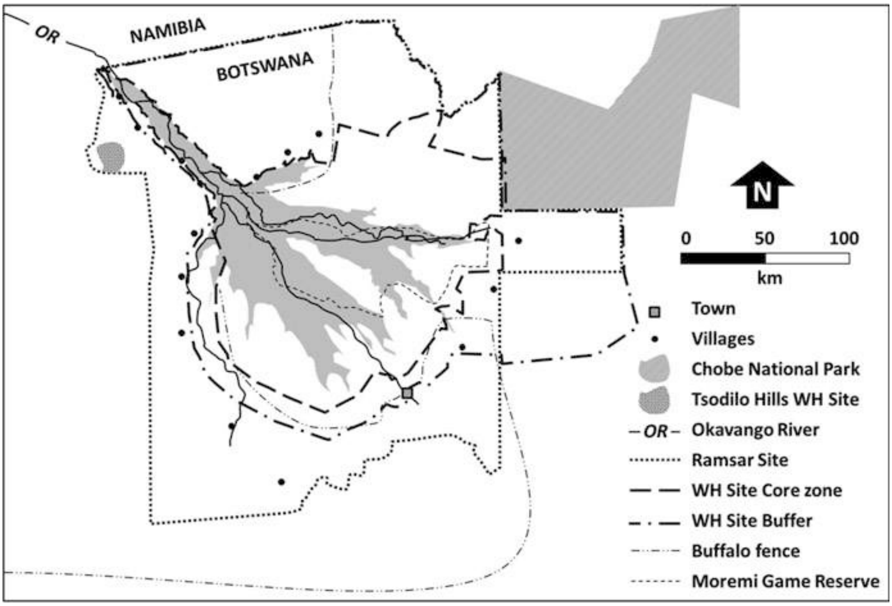

Fig. 1 The administration and legal boundaries within and around the Okavango Delta. Note the location of villages and one town at the fringe of the Delta but beyond the areas reserved for wildlife

increased pressure in all the three riparian states to use the water of the Okavango River for various economic development purposes. While Botswana has modest plans for local domestic use the two upstream countries have large plans for consumptive use of the river water for in particular irrigation but also for diversion and hydro-electric power production (OKACOM 2011b, c, d). Counter to this, strong forces have emerged that want to preserve the Delta.

The reasons for the outstanding biology of the Delta, in contrast to its surroundings, have not been fully understood until the last two decades, but are due to two unique – or very unusual – biogeochemical processes of flood switching and desalination that are vital for the very existence and maintenance of the biological system. These two processes in turn are caused by a very rare combination of (at least) five geographic, geologic, and hydrologic features and processes of which only one takes place in the Delta itself. Firstly, the Delta is located on an extension of the Great East African Rift System, a sand-filled graben more than 100 m deep and slowly sinking. The other four features are those of the inflowing Okavango River that has a pronounced seasonal flood pulse causing the flooding of the Delta, is a carrier of fine sediments, has low nutrient concentrations, and has a very high bicarbonate concentration. These are the features that need to be protected for an effective conservation of the Delta.

The Permanent Okavango River Basin Water Commission (OKACOM) 1994-

In 1994 the three riparian countries of the Okavango River system signed an agreement to work for joint planning, management, and information sharing regarding the river basin and to form a joint commission for that purpose: the Permanent Okavango River Basin Commission (OKACOM 1994). The two upstream countries Angola and Namibia were predominantly interested in water withdrawals for domestic use and irrigation as well as to construct hydroelectric power plants, where 17 suitable sites had been identified in Angola and one in Namibia. Botswana on the other hand, as the end user, emphasized the need for water for conservation of the Okavango Delta.

The OKACOM agreement concerns joint monitoring, data sharing, and planning of resource use; prior reporting on plans that might affect the water resources of the basin; and consensus between the three states before any actions are taken. A major aim of OKACOM was to develop a joint development and management plan for the river basin with emphasis on sharing of the water. This work progressed very slow partly due to the civil war in Angola and partly due to lack of trust between the parties. This caused a serious crisis in 1996.

After several years of drought, in 1995 Namibia started to plan for a forced construction of a pipeline from the Okavango River up to their highland channel system that would deliver the water to the capital Windhoek (Ramberg 1997). This was done as an “emergency situation” with reference to the Helsinki rules and without prior consultation with Angola and Botswana. It caused very strong reactions in Botswana, and one of the countermeasures became to unilaterally ratify the Ramsar Convention in 1996 and declare the Okavango Delta a Ramsar site: a wetland of international importance, which was endorsed by the convention in 1997.

Fortunately, the drought ended with good rains in the beginning of 1997, and the construction of the pipeline was put on hold.

In spite of problems, the OKACOM continued to meet, and from the beginning of the new millennium, it has made considerable progress and trust between the three parties has improved. Existing knowledge on the whole river basin regarding its hydrology, geography, biology, and social and economic factors has been collected and reported (OKACOM 2011a) in a transboundary diagnostic analysis (TDA) document. A permanent secretariat has been established in Maun that handles communication, information, documentation, and organizational matters. The commission meets at least once a year, and a number of joint technical subcommittees are established.

After the TDA report three National Strategic Action Plans (NAP) have been developed (OKACOM 2011b, 2011c, 2011d) and based on all four documents a Strategic Action Plan (SAP) for the whole system (OKACOM 2011e) has been produced.

Southern African Development Community (SADC) 2000

The democratic transition in South Africa between 1990 and 1994 vitalized the collaborative work in the Southern African Development Community (SADC) that organizes the 15 southernmost states in Africa, including the three riparian countries sharing the Okavango Basin. A number of binding protocols has been developed, among them the Revised Protocol on Shared Watercourses in the Southern African Development Community (SADC 2000), of which there are several within the region. The organization, communication, and mode of operation of shared river commissions within the SADC is outlined. Importantly, it is specific on prior reporting about planned impacts, how these should be done, and how disputes between parties sharing a water resource should be resolved. Consensus between the parties is a cornerstone principle. It thus overlaps and overarches the OKACOM agreement.

The Ramsar Convention 1997

After the gazetting by the Ramsar Convention of the Okavango Delta as a "Wetland of International Importance" in 1997, the government of Botswana started to develop – as a condition of the Ramsar Convention – an Okavango Delta Management Plan (ODMP). This involved all relevant government departments and the Tawana Land Board (see below) under the leadership of a temporary project management structure within the newly formed Department of Environmental Affairs. It was a huge effort with several hundred meetings between government departments, various technical subcommittees, and consultants on one hand and on the other hand more than 150 consultations with stakeholders including local communities, tourism operators, etc. The planning project was finalized in 2008 (DEA 2008) and the planning structures dissolved.

Formally, it then became the responsibility of the Department of Environmental Affairs to implement the ODMP, but each of 11 subdepartments is in charge of its normal area of responsibility such as departments of water affairs, wildlife and national parks, tourism, livestock, and animal production. The jurisdiction of the land itself however is under the Tawana Land Board that is a traditional tribal authority that allocates land for a limited period to different users, and no land within the whole North-Western District can be bought or sold.

The gazetting and demarcation of the Ramsar site did therefore not change the traditional power sharing between these authorities; it just placed a larger frame around older legal and physical ones (Fig. 1). An important element is the buffalo fence – for which the Department of Livestock and Animal Production is responsible – that surrounds the eastern and southern parts of what is normally considered as the Okavango Delta. Its aim is to prevent wildlife-vectored diseases to spread into livestock. No permanent settlements are allowed either. There are, however, two old villages, and a number of "service villages" are emerging adjacent to tourist camps.

The Moremi Game Reserve of 5000 km^2 (including a small part of Chobe National Park, Fig. 1) in the east and central parts of the Delta was gazetted by the Tawana tribe during the 1940s. This is now the core of the Ramsar site and targeted for wildlife protection. Game-viewing tourism is however allowed and about 16 tented camps have been erected. This area is managed by the Department of Wildlife and National Parks and entrance fees are charged.

Outside this area and roughly up to the buffalo fence (Fig. 1), the Delta is subdivided into 29 Wildlife Management Areas (WMAs) meant as a buffer zone of 13,000 km^2, where sustainable use of wildlife resources is allowed, but no permanent settlements are permitted. Of the WMAs, 13 are given to local communities; the rest are tendered for and leased out to tourist operators. All are used either for scenic tourism or for safari hunting. The hunting quotas are set by the Department of Wildlife and National Parks, and traditional harvesting by local villagers of natural resources such as wood, reeds, thatching grass, and fish is allowed, which is mainly supervised by the Tawana Land Board.

The total area of the Okavango Delta Ramsar site is 68,640 km^2 of which about 26% – most of the Okavango Delta – is devoted to wildlife conservation. The rest, mostly dry Kalahari savanna, is used for small-scale agriculture or low-intensity livestock ranching. Notably the Ramsar site has borders in common with national parks in Botswana and Namibia and one small Ramsar site at the Okavango River inlet (Fig. 1) adding another 19,000 km^2 to a common wetland conservation area, connecting the hydrologic- and biologic-related Okavango and Zambezi river systems.

UNESCO World Heritage Site

In 2014 the Okavango Delta was inscribed as a UNESCO World Heritage Site on the initiative of Botswana. The designated area of 20,000 km^2 and an additional 23,000 km^2 as a buffer zone, is considerable (Figure 1) but smaller than that of the Ramsar Site, mainly because it avoids areas that could be exploited (such as by mining). All the three riparian countries are members of UNESCO and the effective protective power of both the World Heritage status as well as the designation as a Ramsar Site demonstrate their willingness to be good and proactive members of the world community.

Conclusions

On the national level Botswana has put in place a set of policies and laws that define the user status of wildlife management areas, game reserves, and national parks that encompass practically the whole Delta (Fig. 1). In any of the user categories the emphasis is on conservation. The two international agreements, the Ramsar

Convention and the UNESCO World Heritage Convention put emphasis on conservation but are restricted to the Delta itself (Fig. 1) and address only in passing the need to maintain the integrity of the drainage basin.

Although the Delta itself is shielded by an almost overwhelming blanket of protective policies, the properties of the inflowing river water, its quantity and quality, are not protected by any policy. It is however the unique features of this inflow that create and maintain the exceptional features of Okavango Delta (Ramberg and Wolski 2008). The two collaborative agreements of a regional character – OKACOM and SADC – put emphasis on *water use and water sharing* in the whole river basin. These are the structures where politics and policies are formed that decide the fate of the Okavango Delta and the wider river basin.

In the Transboundary Diagnostic Analysis (OKACOM 2011a; King and Chonguica 2016), a hydrologic-economic analysis has been made for three levels of water utilization in the drainage basin based on national plans for irrigation, hydroelectric dams, and water diversions. All three scenarios predict net economic losses and severely so for the medium- and high-level alternatives. Reduced flooding of the Delta and loss of tourism revenue in Botswana – its second largest income earner – are the major reasons, but economic gains in the upstream exploiting countries are likely to be negative due to poor soils, poor infrastructure, and remoteness. In spite of this the national strategic action plans (NAP) published after the TDA report, the plans for Angola and Namibia put emphasis on the development of irrigation and water diversion. Thereafter a joint SAP for the whole river basin has been produced by OKACOM (2011e) but was not made public until the end of 2016. The emphasis of this agreement is to continue to strengthen administrative and management structures, to start environmental monitoring in the whole drainage basin, to improve forecasts and models, and to develop a joint vision for the future of the Okavango system (King and Chonguica 2016). No exploitive measures, such as irrigation or water diversions, are considered or even mentioned. However, in the same document it is clearly stated that the ambition to pursue the exploitive projects as planned in the National Action Plans (NAPs) remains unchanged, "The implementation of the NAPs moves forward and independently of the SAP process. . . ." In these national plans there is also an ambition to move fast and interventions within the drainage basin might have already happened as there is no definitive information about the status since 2010.

Both the OKACOM TDA and the SAP documents reflect a lack of understanding of the uniqueness of the Delta, in particular the vital importance of flood switching and desalination. The unpredictability of flooding is described as a major problem that ought to be controlled, while its vital role for the biologic functioning of the Delta is not emphasized. The absolute critical function of desalination is not mentioned at all, although the magnitude of its importance in maintaining the fresh water nature of the Delta is immense. The sensitivity or fragility of this process is now impossible to predict with any certainty as there are limited in-depth studies and, due to the uniqueness of the Delta, no comparable systems.

It must be emphasized that the planned, proposed, or already ongoing intrusions if fully implemented will significantly reduce river flow and cause a number of changes in the water quality as well, which is likely to cause a sudden collapse and a complete change of the nature of the Delta (Ramberg 2016; Ramberg and Wolski 2008).

European Union Natura 2000

70

Robert J. McInnes

Contents

Abstract

Natura 2000 is the centerpiece of European Union (EU) nature and biodiversity policy. It is an EU-wide network of nature protection areas established under the 1992 Habitats Directive. The aim of the network is to assure the long-term survival of Europe's most valuable and threatened species and habitats. It is comprised of Special Areas of Conservation (SACs), designated by member states under the Habitats Directive, and also incorporates Special Protection Areas (SPAs) which they designate under the 1979 Birds Directive. The establishment of the Natura 2000 network of protected areas also fulfills a European community obligation under the United Nations Convention on Biological Diversity (CBD). Today, the network comprises over 25,000 sites representing 18% of the area of the member states of the European Union.

Background

Natura 2000 is the centerpiece of European Union (EU) nature and biodiversity policy. It is an EU-wide network of nature protection areas established under the 1992 Habitats Directive (EC 1992). The aim of the network is to assure the long-term survival of Europe's most valuable and threatened species and habitats. It is comprised of Special Areas of Conservation (SACs), designated by member states under the Habitats Directive, and also incorporates Special Protection Areas (SPAs) which they designate under the 1979 Birds Directive (EC 1979). The establishment of the Natura 2000 network of protected areas also fulfills a European community obligation under the United Nations Convention on Biological Diversity (CBD). Today the network comprises over 25,000 sites representing 18% of the area of the member states of the European Union.

Natura 2000 is not a system of strict nature reserves where all human activities are excluded. The network includes many nature reserves; however most of the land is privately owned, and the emphasis is on ensuring that future management is sustainable, both ecologically and economically.

Natura 2000 applies to bird sites (SPAs) and to habitat sites (SACs), which are divided into biogeographical regions. It also applies to the marine environment.

Bird Sites

The identification and delimitation of SPAs is based on scientific criteria such as "1% of the population of listed vulnerable species" or "wetlands of international importance for migratory waterfowl." Hence, there is considerable overlap with designated Ramsar sites. Member states have a margin of discretion in determining the most appropriate criteria. However, they must then fully apply those criteria in a way that ensures that all the "most suitable territories," both in number and surface area, are designated. On the basis of information provided by the member states, the European Commission determines if the designated sites are sufficient to form a coherent network for the protection of the vulnerable and migratory species.

Habitat Sites

SACs are established with the aim to protect the 220 habitats and approximately 1,000 species listed in Annex I and II of the directive which are considered to be of European interest following criteria given in the directive (EC 1992). Under the Habitats Directive, there are three stages in the selection of SACs:

1. The responsibility for proposing sites under the Habitats Directive lies with the member states. Each state carries out comprehensive assessments of each of the habitat types and species present on their territory. The choice of sites is a purely

scientific process, based on standard selection criteria specified in the directive. Site-specific data are communicated to the Commission by using Standard Data Forms.

2. On the basis of the proposed national lists, the Commission, in agreement with the member states, must adopt the lists of "Sites of Community Importance." Scientific seminars are then convened by the Commission for each biogeographical region in order to analyze the member states' proposals in a transparent way. They are open to the member states concerned and to experts representing relevant stakeholder interests, including owners, users, and environmental NGOs. These seminars are supported by the European Environment Agency, assisted by the European Topic Centre on Biological Diversity which is based in Paris, France. These expert seminars aim to establish if sufficient high-quality sites have been proposed by each member state to ensure the favorable conservation status of each habitat type and species throughout their range in the EU. The objective is to establish a list of "Sites of Community Importance" for each of the regions determined by the Habitats Directive, applying a consistent approach across the member states.
3. Once the lists of "Sites of Community Importance" have been adopted, it is for the member states to designate all of these sites as "Special Areas of Conservation," as required by the Habitats Directive, as soon as possible and within 6 years at the most. They should give priority to those sites that are most threatened and/or that are of most importance in conservation terms. During this period, member states must take the necessary management or restoration measures to ensure the favorable conservation status of those sites.

Biogeographical Regions

The Habitats Directive divides the EU into nine ecologically coherent "biogeographical" regions – the **Atlantic**, **Continental**, **Alpine** (which includes the Pyrenees, the Alps, the Carpathian Mountains, and parts of Scandinavia), **Mediterranean**, **Boreal** (Finland, Sweden, Estonia, Latvia, and part of Lithuania), the **Macaronesian** (Madeira, Azores, and Canary Islands), the **Pannonian** (essentially Hungary and parts of the Czech Republic, Romania, and Slovakia), the **Steppic,** and the **Black Sea** Region (parts of Bulgaria and Romania). Natura 2000 sites are selected according to each biogeographical region. Working on this level makes it easier to conserve species and habitat types under similar natural conditions across a suite of countries.

Future Challenges

The development of the Natura 2000 network has not been without considerably scientific and political challenges (Keulartz and Leistra 2008); however it is now moving toward the delivery of a coherent and robust network of protected sites.

But designation remains the starting point for sites, rather than the end. Sites still require protection from loss and damage and monitoring to assess the effectiveness of protection (Evans 2012). A serious future challenge will be the response of member states to a changing climate and especially the squeeze on coastal sites as a result of the dual pressures of a rising sea level and development pressures.

Background

Across Europe, rivers, lakes, and coastal waters are vital natural resources which provide drinking water for humans, provide habitats for many different species of wildlife, and are an important resource for inter alia agriculture, industry, and recreation. Through generations of misuse, a significant proportion of these wetlands have become degraded or threatened. The future protection and improvement of the water environment has been recognized at the European Union (EU) level as being an important component of achieving sustainable development and vital for the long-term health, well-being, and prosperity of European citizens.

In October 2000 the “Directive 2000/60/EC of the European Parliament and of the Council of 23 October 2000 establishing a framework for Community action in the field of water policy” (European Commission 2000) (or in short the *Water Framework Directive* or WFD) was adopted and came into force in December 2000. The purpose of the Directive is to establish a framework for the protection of inland surface waters (rivers and lakes), transitional waters (estuaries), coastal waters, and groundwater. It aims to ensure that all aquatic ecosystems and, with regard to their water needs, terrestrial ecosystems and wetlands meet “good status” by 2015.

The WFD improved on earlier, piecemeal EU water legislation and expanded the scope of water protection to all waters (Chave 2001). The WFD also adopted the most appropriate model for a single system of water management, namely, the river basin. River basins are the natural geographical and hydrological unit and therefore the logical basis for water management, as opposed to working with administrative or political boundaries. In the development of the WFD, initiatives developed by the states concerned for the Maas, Scheldt, or Rhine river basins have served as positive examples of this approach, with their cooperation and joint objective setting across member state borders or in the case of the Rhine even beyond the EU territory. While several member states were already adopting this approach, it was recognized that this was not universal across the EU.

For each river basin district, several of which traverse national frontiers, the Directive requires a cyclical process where river basin management plans are prepared, implemented, and reviewed every 6 years. The first cycle covers the period

2009–2015. Within the river basin management process, there are four distinct elements: the characterization and assessment of impacts on river basin districts, the environmental monitoring, the setting of environmental objectives, and the design and implementation of the program of measures needed to achieve them.

Horizontal Guidance on the Role of Wetlands in the WFD

The WFD clearly identifies the protection, restoration, and enhancement of the water needs of wetlands as part of its purpose. Article $1_{(a)}$ of the WFD states that:

> The purpose of this Directive is to establish a framework for the protection of inland surface waters, transitional waters, coastal waters and groundwater which:
> (a) prevents further deterioration and protects and enhances the status of aquatic ecosystems and, with regard to their water needs, terrestrial ecosystems and wetlands directly depending on the aquatic ecosystems.

However, the Directive failed to provide any specific definition for wetlands. Similarly, the Directive does not state clearly or explicitly the extent to which wetlands should be used for the achievement of environmental objectives. Member states and stakeholders felt that it would be helpful to explore and clarify the role of wetlands in implementing the Water Framework Directive. Therefore a Common Implementation Strategy guidance document was developed, in which the pressures on wetlands were acknowledged, and their potentially important roles in river basin management, and particularly in helping to achieve WFD environmental objectives, were clarified. This resulted in the preparation and publication of *horizontal guidance on the role of wetlands in the WFD* (European Union 2003).

Aspects of implementation are clearly described in the horizontal guidance document including where the appropriate use of wetland protection and restoration could help to fulfill environmental objectives in a cost-effective and sustainable manner. The document also acknowledged that wetlands are a crosscutting issue and elaborated a common understanding of the WFD requirements regarding wetlands and their role in its implementation. In some cases, where additional effort could lead to considerably enhanced results, the horizontal guidance goes one step further and illustrates best practices beyond the legal requirements of the WFD while recognizing that member states have the flexibility to establish stricter environmental protection according to their particular national concerns and situations.

The WFD and the associated horizontal guidance do not seek to establish a new international definition of wetlands for the purposes of the Directive. Rather, the guidance explains the relevance of wetlands to the achievement of the Directive's environmental objectives. Key within this approach is the attention given to key relationships among significant elements of the hydrological network and the role of wetlands with respect to this approach.

It could be argued that the Directive is lacking in two principal areas in relation to wetlands. Firstly, while the Directive refers to wetlands (Recitals 8 and 23, Article $1_{(a)}$, and Annex $VI_{(vii)}$), it does not provide a definition for them or provide a size range to indicate their dimension. Secondly, the Directive does not set specific obligations or recommendations for wetlands or other terrestrial ecosystems per se. However, the environmental objectives of the WFD are to be applied to, and monitored through, "water bodies"; therefore it is important for member states to have a clear understanding of the relationship between water both surface and groundwater bodies and wetlands, in order to understand how these systems might be encompassed within the cycle of river basin planning (European Union 2003).

The Directive sets out the following environmental objectives for water bodies:

- Preventing deterioration in status
- Achieving good surface water status or, for artificial or heavily modified surface water bodies, good ecological potential and good surface water chemical status
- Good groundwater status
- Any less stringent objective applicable under Article 4.5

The focus of the WFD on water bodies, and particularly their relationships within a river basin, helps to emphasize the functional role of wetland systems within the wider hydrological cycle. This is reflected in the Directive by means of a complex set of provisions which are illustrated in Fig. 1.

Figure 1 illustrates the various different ecosystems that may be present in a river basin district and which may be relevant to the achievement of the Directive's objectives. The relative sizes and overlaps of the ellipses depend on the sorts of ecosystems present within each river basin district. The central ellipse represents the "universe" of wetlands and demonstrates its reach into the various component ecosystems. The following sections of the guidance describe the role of these different ecosystems in the river basin management planning process.

The nature of the role of each single category of wetland typology identified in Fig. 1 is described in more details below.

Surface Water Bodies (River, Lake, Transitional, and Coastal Waters)

These can be divided into two systems:

(a) **Wetland ecosystems identified as water bodies**
Many wetland ecosystems are mosaics of surface water, permanently and temporarily inundated or waterlogged land, such as lowland mire systems or floodplain wetlands. WFD provisions in relation to surface waters directly help to protect and enhance these wetland ecosystems through their designation as water bodies, and by setting objectives for them, where they fall within the WFD categories of rivers, lakes, and transitional or coastal waters.

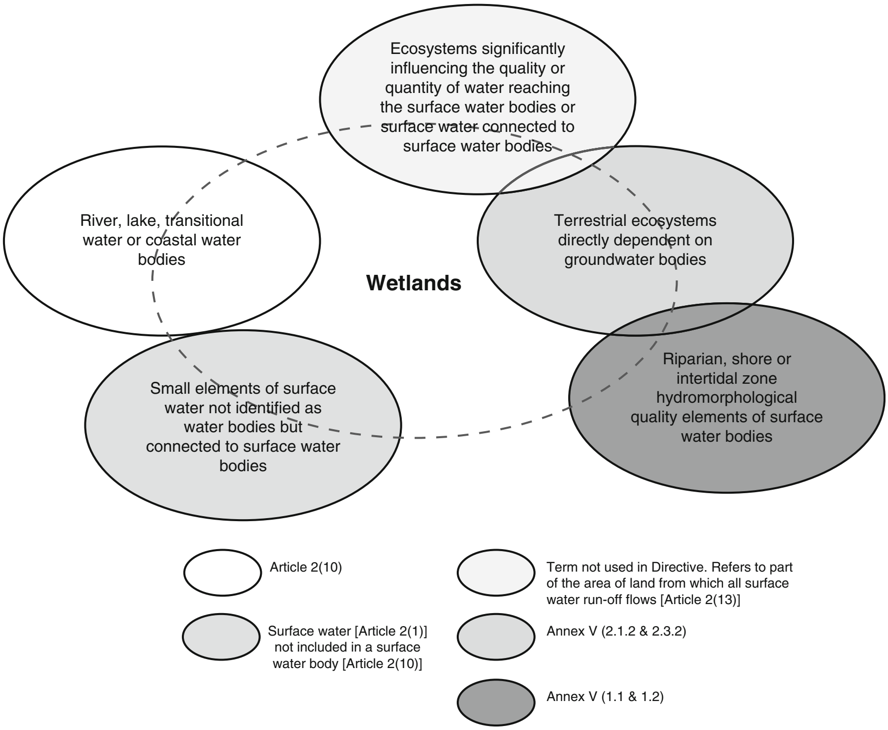

Fig. 1 Ecosystems relevant to the achievement of the Directive's objectives

(b) **Riparian, shore, and intertidal zone quality elements of surface water bodies**
The hydromorphological quality elements of surface water bodies include the structure and condition of the riparian zone of rivers, the shore zone of lakes, and the intertidal zones of transitional and coastal waters. These zones can include ecosystems which are widely regarded as wetlands, where the structure and condition of such wetlands is relevant to the achievement of the objectives for a surface water body.

Ecosystems Significantly Influencing the Quality and Quantity of Water Reaching Surface Water Bodies or Surface Waters Connected to Surface Water Bodies

Ecosystems which are adjacent to, or contiguous with, water bodies and which may influence the status of those water bodies should be encompassed within the riparian, lakeshore, or intertidal zones (above), in order to ensure effective operation of WFD environmental objectives. However, there may be other wetland ecosystems within river basins which are not adjacent to water bodies and therefore do not form part of the riparian, shore, or intertidal zones, which may influence the quality and quantity of water reaching those bodies or reaching small elements of surface waters connected to those bodies. Member states need to ensure that the quality and quantity of water entering surface water bodies via these disparate wetland ecosystems is such as to ensure the achievement of the relevant objectives for the water bodies. In doing so, member states may determine where appropriate or necessary to manage relevant activities on, protect, enhance, restore, or even artificially create these wetlands.

Terrestrial Ecosystems Directly Depending on Groundwater Bodies

The Directive's objectives of achieving good groundwater quantitative status and good groundwater chemical status require inter alia that the groundwater needs of terrestrial ecosystems that are directly dependent on bodies of groundwater are protected and, where necessary, restored to avoid or remedy significant damage to such ecosystems. The terrestrial ecosystems that depend directly on a body of groundwater will include types of systems that occur in areas where the water table is at or near the surface of the ground, or, in other words, wetlands.

Small Elements of Surface Water Connected to Water Bodies but Not Identified as Water Bodies

There are major practicality issues in identifying every element of surface water in a river basin district as a water body or part of a water body. Member states have to decide within the river basin management planning process which elements of surface water are not sufficiently discrete and/or significant to be identified as water bodies. Many of the elements of surface water that are not identified will nevertheless be important elements in wider hydrological cycles and potentially connected to surface water bodies. Such elements need to be protected or, in some cases, enhanced and restored to ensure that anthropogenic impacts do not compromise the achievement of the environmental objectives of the water bodies to which they are connected. In some cases, member states may even choose to artificially create such surface waters where they determine that this is an appropriate or necessary means of achieving the objectives of the Directive for surface water bodies. An example of this would be the creation of constructed wetlands to mitigate the impacts of urban or agricultural runoff on river water bodies.

Future Challenges

Considerable progress has been made on the implementation of the WFD (European Union 2010). However, significant challenges remain to fully achieve the ambitious objectives of the Directive. Some of these challenges revolve around the degree of fit within institutional structures and practices (Moss 2004), while others relate both directly and indirectly to wetland management issues.

For instance, the concept of environmental flows is well established in wetland science and literature. However, the WFD does not explicitly use the term environmental flows but requires member states to achieve good ecological status in all water bodies through an assessment of aquatic biology. Nevertheless, it is accepted that to meet ecologic targets requires appropriate hydrological regimes to be in place. Therefore the implementation of environmental flows will be a key measure for restoring and managing river ecosystems and delivering on the WFD objectives (Acreman and Ferguson 2010).

Similarly, wetlands, as small elements of surface water bodies, can play a key role in mitigating the impacts of agricultural pollution (Harrington and McInnes 2009). However, results of economic modeling from the Upper Ems river basin in northwestern Germany have shown that drastic measures, which include wetland protection, are unrealistic from a socioeconomic point of view. To achieve the water quality target in the basin would require not only an increase in the area of protected wetlands from 0% to 9%, but accompanied land-use changes such as a reduction of arable land from 77.2% to 46%, an increase of pasture from 4% to 15%, and afforestation from 10% to 21% (Volk et al. 2009). Furthermore, there are additional barriers to the integration of wetlands into programs of measures through the failure of traditional environmental accounting. A study from the River Elbe demonstrates that riparian wetlands provide significant benefits that should be considered in river basin management decisions; however these are often neglected leading to biased cost–benefit analysis results and therefore misguided the decision-making processes (Meyerhoff and Dehnhardt 2007).

North America Transnational Legal Frameworks

72

Alicia Cate

Contents

Abstract

There are a number of legal frameworks that directly or indirectly affect wetlands management in North America. All are designed to promote transnational cooperation to protect, conserve, and manage wetlands. These legal frameworks include regional agreements that encompass the three countries of North America (Canada, Mexico, and the United States), as well as bilateral agreements between Canada and the United States and the United States and Mexico in relation to transboundary waters.

Introduction

There are a number of legal frameworks that directly or indirectly affect wetlands management in North America. All are designed to promote transnational cooperation to protect, conserve, and manage wetlands. These legal frameworks include regional agreements that encompass the three countries of North America (Canada, Mexico, and the United States) as well as bilateral agreements, between Canada and the United States and the United States and Mexico in relation to transboundary waters.

Regional Agreements

1988 U.S.-Mexico-Canada Tripartite Agreement on the Conservation of Wetlands (Tripartite Agreement)

The historical underpinnings of the Tripartite Agreement are found in the Convention for the Protection of Migratory Birds signed between the United States and Great Britain (representing Canada) in 1916, which was created to counteract the decline in migratory bird populations due to unregulated harvesting for meat and plumage, among other uses. International cooperation to protect migratory birds was expanded to include Mexico in 1936 as well as Japan in 1972 and the Soviet Union in 1978. In 1986, a desire to protect declining populations of migratory waterfowl led to the North American Waterfowl Management Plan signed between Canada and the United States. Mexico joined this collaborative effort in 1988 via the Tripartite Agreement, which was signed by the directors of the three federal wildlife agencies in order to create a management plan to restore and maintain not only waterfowl populations but also the wetlands habitat that was critical for waterfowl as well as other wetland-dependent wildlife. The North American Waterfowl Management Plan envisioned collaborative conservation in the form of Joint Ventures whereby government agencies, nonprofit organizations, corporations, tribes, and/or individuals would plan, fund, and implement projects to conserve high priority bird habitat, including wetlands. Since the first Joint Venture was created in 1987, a total of 24 Joint Ventures have been created that geographically cover nearly all of Canada and the United States and much of Mexico (USFWS, Joint Venture Map 2014a). A number of these Joint Ventures have focused on conservation of wetlands that stretch across borders, including the Pacific Coast Joint Venture, the Rio Grande Joint Venture, and the Sonoran Joint Venture (USFWS, Joint Venture Directory 2014b; Pacific Coast Joint Venture 2014; Rio Grande Joint Venture 2014; Sonoran Joint Venture 2014).

North American Agreement on Environmental Cooperation (NAAEC)

The NAAEC was negotiated in conjunction with the North American Free Trade Agreement (NAFTA) and came into force at the same time on January 1, 1994 (CEC, About the CEC 2014a). As noted in the listed objectives in Article 1 of the NAAEC, one of the goals was to "increase cooperation between the Parties to better conserve, protect, and enhance the environment, including wild flora and fauna," (USTR, NAAEC 1994). The NAAEC established the Commission for Environmental Cooperation (CEC), an international organization to support cooperation among the NAFTA Parties to address environmental issues across North America. Over the past 20 years, the environmental ministries of the three countries have funded the work of the CEC, which in turn has coordinated a cooperative program of environmental work. A number of the cooperative programs have touched on wetlands management. For example, a collaborative study was done to examine the extent and dynamics of carbon sequestration of blue carbon ecosystems in North America, including coastal wetlands (CEC, North America Blue Carbon Scoping Study 2014b). As blue carbon ecosystems, including coastal wetlands, have been found to store two to four times more carbon in their vegetation and soils than mature tropical forests, these ecosystems create the potential for carbon offset payments when they are conserved or restored in the context of developing carbon markets (NOAA 2014).

Bilateral Agreements

Canada and the United States

Canada and the United States have entered into bilateral agreements related to transboundary waters, such as the Boundary Waters Treaty (BWT), which dates back to 1909. The BWT sets forth general principles to be followed by the two nations in relation to commerce, navigation, water use, diversion, and obstruction with the aim of preventing and/or resolving issues related to shared waters. The BWT established the International Joint Commission (IJC), which consists of three appointed independent experts from each country who regulate shared water usage, investigate transboundary issues, and recommend solutions (IJC, BWT 1909). The IJC's guiding principles include a focus on sustainable development, an ecosystem approach, elimination of persistent toxic substances, sound science and, where necessary, a precautionary approach (IJC, Guiding Principles 2014a). The IJC's regulation of shared water uses, including decisions regarding water level and flow across the boundary, has a direct affect on wetlands management. In addition, the IJC has reporting requirements under the Great Lakes Water Quality Agreement (GLWQA), which was signed by Canada and the United States in 1972 and later amended several times to address additional environmental concerns related to the waters in and around the Great Lakes, including the surrounding wetlands (IJC, Mission and Mandates 2014b). Article 3 of the 2012 Protocol to the GLWQA includes the objective of "support[ing] healthy and productive wetlands" (IJC, GLWQA 2012). In the 15th Biennial Report on Great Lakes Water Quality, the IJC focused on the nearshore zones of the Great Lakes and made a number of recommendations to address threats to nearshore water quality, including the use of

Lakewide Water Management Plans that would encompass wetlands (IJC, 15th Biennial Report 2011).

Mexico and the United States

There are several treaties between Mexico and the United States dating back to 1848 that focus on delineating the boundary between the two countries in relation to the river systems along the border (IBWC, Treaties Between the United States and Mexico 2014a). The 1944 Treaty, entitled "Utilization of Waters of the Colorado and Tijuana Rivers and of the Rio Grande," forms the basis for regulating shared waters. Article 3 of the 1944 Treaty entrusts the International Boundary and Water Commission (IBWC) with the regulation of joint use of the waters, including for "beneficial uses which may be determined by the Commission" (IBWC, 1944 Treaty). The IBWC is an international body composed of a United States Section (staffed by the U.S. Department of State) and a Mexican Section (staffed by the Secretariat of Foreign Relations of Mexico). Each section is headed by an Engineer-Commissioner appointed by his/her respective President. The IBWC implements the boundary and water treaties, including the 1944 Treaty, through cooperative projects and attempts to resolve any disputes that may arise under the various treaties (IBWC, About Us 2014b). By way of example, in March 2014, thanks to a landmark agreement between the United States and Mexico under the 1944 Treaty known as "Minute 319" and the related cooperative project coordinated by the IBWC and a binational coalition of nongovernmental organizations, a pulse flow of approximately 105,000 acre-feet of water from the Colorado River will mimic the natural spring floods and inundate the wetlands in the delta region for the first time since 1960 (IBWC, Minute 319 November 2013; National Geographic, Water Currents 2014).

Future Challenges

While the decline in wetlands acreage in North America is less precipitous than the period prior to the 1970s, the decline continues in many areas due to many pressures including urban development and farming (EPA 2014). As wetlands supply vital ecosystems services such as filtering out pollutants, absorbing excess rainwater to prevent flooding, and providing vital wildlife habitat, legal frameworks for collaborative efforts in North America will need to address how to value these ecosystem services such that the continued existence of the wetland is more valuable than draining and filling for development.

Climate change poses a number of significant impacts on wetlands, including altered hydrology, such as flooding and drought, erosion, spread of invasive species, and extended range for pest and disease vectors (Erwin 2008). In light of this, current collaborative efforts will need to devote more focus and funding on climate adaptation in order to conserve and restore the wetlands of North America.

Abstract

Projected changes in the climate are expected to increase temperatures, modify precipitation, raise sea levels, and increase extreme climate events with large impacts on wetlands, including their occurrence and extent, vegetation structure, ecological processes and functions, as well as the livelihoods and wellbeing of the people that depend on the wetlands and their ecosystem services. Some changes in wetland species have already been observed with both freshwater and marine species shifting their geographic ranges, seasonal activities, and migration patterns. At the same time it has been recognized that some wetlands store and

Introduction

The Intergovernmental Panel for Climate Change (IPCC) has provided regular assessments on the consequences of climate change on ecosystems based on thorough assessments of published information. The Fifth Assessment Report (IPCC 2014) has documented information about the impact of change in climate on natural systems including wetlands, both inland and coastal/marine, as well as on the quality and quantity of the hydrological systems that are so important for wetlands. Projected changes in the global climate are expected to increase temperatures, modify precipitation, raise sea levels, and increase extreme climate events with large impacts on wetlands, including their occurrence and extent, vegetation structure, ecological processes and functions (Junk et al. 2013), as well as the livelihoods and wellbeing of the people that depend on the wetlands and their ecosystem services (Finlayson et al. 2006; Horwitz et al. 2011). Some changes in wetland species have already been observed with both freshwater and marine species shifting their geographic ranges, seasonal activities, and migration patterns (Finlayson et al. 2006). At the same time it has been recognized that some wetlands store and emit greenhouse gases with their degradation and destruction contributing to greater releases of such gases and negative implications for atmospheric temperatures (Lloyd et al. 2013).

In response to these scenarios, Junk et al. (2013) undertook a continental/regional analysis of the likely impacts of climate change on wetlands. This was based on individual analyses undertaken for North and Central America (Mitsch and Hernandez 2013), South America (Junk 2013), Africa (Mitchell 2013), East and High Asia (An et al. 2013), tropical Asia (Gopal 2013), Europe (Čížková et al. 2013), Russia (Robarts et al. 2013), and Australia (Finlayson et al. 2013). In doing this it was noted that the current distribution and extent of wetlands no longer coincided closely with that which previously existed as a consequence of conversion and loss (MEA 2005; Davidson 2014) and the alteration or replacement of others, such as the construction of rice paddy in many parts of Asia in particular. In this respect, climate change was seen as an additional pressure on wetlands that were already under severe pressure (MEA 2005). Further, the extent of wetlands in many regions is still poorly known with inadequate inventory (Finlayson et al. 1999; Finlayson 2012), including within large basins such as the Amazon (Junk 2013), and limited understanding of the important role that wetlands have played in sustaining human health and wellbeing (Horwitz et al. 2011).

The following text addresses the vulnerability of wetlands to climate change, the likely effects at a regional/continental scale, the more specific effects on migratory and nomadic waterbirds given their reliance on multiple wetlands, and finally a discussion on adaptation or responses to such effects.

Mitigation of Climate Change

Mitigation in the context of wetlands and climate change describes any action that prevents, reduces, or slows climate change and can be achieved either by reducing greenhouse gas emissions from wetlands or by enhancing the capacity of wetlands to act as greenhouse gas sinks. The importance of carbon storage and emissions from wetlands, in particular from temperate or tropical peatlands, and coastal wetlands, such as salt marshes, mangroves, and seagrass beds, is increasingly being recognized. It is well known that many wetlands contain large stores of carbon, much of it laid down over centuries, and if these were drained or otherwise converted, large amounts of carbon in the form of greenhouse gases will be released to the atmosphere and contribute to further climate change. This is well known for peatlands, both forested and nonforested. Tropical forested peatlands in particular have received a great deal of attention, with more recent and thorough investigations reducing some of the uncertainties associated with previous estimates (Page et al. 2011). Under existing land use practices it is expected that subsidence and carbon loss from tropical peatland is inevitable in oil palm plantations and could end in flooding and loss of agricultural production as well as contributing to the continuing destruction of valuable ecosystems and increased carbon emissions.

The Food and Agriculture Organization of the United Nations and Wetlands International have produced guidance for the management of peatlands, including the identification of finance options, to achieve reductions in emissions and enhance the maintenance of other ecosystem services from peatlands (Joosten et al. 2012). The guidance provides a decision support tree as a guide to opportunities for both cultivated and uncultivated peatlands and outlines methods and data available for quantifying emissions from peatlands and other organic soils to achieve reductions in emissions and enhance the maintenance of other ecosystem services from peatlands.

There has recently been increased attention to the storage of carbon in coastal ecosystems, notably mangroves, tidal saltmarshes, and seagrass beds, which can store large amounts of carbon in the underlying sediment (Herr et al. 2011). There is growing evidence that the management of these “blue carbon” wetlands has the potential to transform global carbon management, contribute to avoiding further loss and degradation of these ecosystems, and provide further incentives for their restoration and sustainable use. Efforts are underway to develop measures, including policies, to encourage the maintenance of the carbon storage function of these wetlands, many of which have been degraded or lost over recent decades.

A range of policies and practices have been introduced to support mitigation activities, including the development of an international fund for Reducing Emissions from Deforestation and Forest Degradation (REDD+) in developing countries. REDD+ includes policies and incentives for developing countries and includes the role of conservation, sustainable management of forests, and enhancement of forest carbon stocks. It also has immense potential for encouraging the management and restoration of wetlands now that it has been expanded to include activities that improve ecosystem services and provide co-benefits to communities and biodiversity (Alexander et al. 2011).

The IPCC is also paying increasing attention to wetlands in relation to greenhouse gases in response to an invitation by the UNFCCC. A Task Force on National Greenhouse Gas Inventories has prepared supplementary guidance to address, as far as possible, the gaps identified in earlier guidelines. These focus on those human activities and management that give rise to anthropogenic emissions or removals by wetlands and includes cross-cutting guidance on organic soils, the rewetting and restoration of peatlands, other freshwater wetlands, coastal wetlands, and constructed wetlands used for wastewater treatment. In 2013 the IPCC produced a supplement to the 2006 Guidelines for National Greenhouse Gas Inventories (Hiraishi et al. 2014).

Increasingly, coastal ecosystems have also been recognized for their role in carbon sequestration and, when degraded, their potential to become sources of carbon emissions. Progress has been made to include these systems in international and national policy and finance mechanisms. The full integration of coastal management activities as part of countries' portfolio of solutions to mitigate climate change has however not yet been fully achieved due to a lack of technical guidance leading to comparable information and scientific results. In response a manual containing standardized methods for field sampling, laboratory measurements, and analysis of blue carbon stocks and flux in coastal ecosystems has been developed.

Vulnerability of Wetlands to Climate Change

The Ramsar Convention on Wetlands has considered the vulnerability of wetlands to climate change and provided a framework for vulnerability assessment (Gitay et al. 2011) as part of its Integrated Framework for Wetland Inventory, Assessment and Monitoring (IF-WIAM). In line with the convention's focus on maintaining the ecological character of wetlands vulnerability assessment was presented "as an approach that can provide information and guidance for maintaining the ecological character of wetlands which are subject to adverse change as a consequence of climate change (including sea level rise), whilst recognising that climate change will interact with the many other anthropocentric pressures on wetlands." Vulnerability was then defined as "*the degree to which a wetland is sensitive to and unable to adapt to or moderate the consequences of climate change and other (anthropocentric) pressures on its ecological character*" and comprised two major components, namely the sensitivity of the system and its adaptive capacity or resilience. Sensitivity was defined as "*the degree to which a wetland is affected, either adversely or* *beneficially, by climate-related stimuli*" and adaptive capacity as "*the ability of a wetland to adjust to climate change, to take advantage of opportunities, or to cope with or moderate the consequences.*"

By bringing together various methods and approaches, a general framework for wetland vulnerability assessment was developed, comprising the following elements: (i) establishing the status of the biophysical and social components of the wetland, including present and recent pressures; (ii) determining the sensitivity and adaptive capacity of the ecological and social components of the wetland to multiple pressures and developing plausible futures; (iii) developing responses to ensure these futures can be achieved; and (iv) monitoring and adaptive management to reach the desired outcomes. Obtaining the necessary information to undertake an effective assessment may not be straightforward given the paucity of spatial and temporal data, at appropriate scales, as a time series to determine the present condition and trends in the condition of a wetland and its sensitivity and adaptive capacity. It is expected that in many instances the assessment will be an iterative process based on qualitative or subjective information and updated or improved as more information becomes available.

Impact of Climate Change on Wetlands

Climate change is likely to affect wetlands and their biota directly (for example, through increased temperatures) and indirectly (for example, through affecting the water regime). The anticipated impacts are expected to be more negative than positive and include (Finlayson et al. 2006): (i) an initial increase in biological production in some mid-latitude regions and a reduction in the tropics and subtropics; (ii) adverse effects on coastal wetlands, including freshwater lagoons, coral reefs, and mangroves; (iii) decreased water availability in many arid- and semiarid regions; (iv) adverse impacts on migratory and nomadic biota that depend on specific ecosystems for feeding and breeding; (v) immediate effects on wetlands in high latitudes and high altitudes as temperatures increase and the permafrost and glaciers, respectively, melt; and (vi) an increased threat of extinction for currently rare or vulnerable species and biota restricted to islands, peninsulas, or coastal areas. The ecological composition of most wetlands is likely to change, depending on the relative ability of the biota to disperse and establish in new locations. The extent and type of other pressures on wetlands is expected to greatly affect the rate of change in response to changes in the climate.

The following regional summary of the expected impact of climate change on wetlands is taken from Junk et al. (2013) and sources therein. More detailed information can be obtained for individual wetlands from the increasing amount of information that has been published over the past few decades, including analyses of the likely impact of sea level rise and larger storm events, and melting of the permafrost and glaciers.

North and Central America (Mitsch and Hernandez 2013)

Melting of the permafrost in the tundra is expected to result in major changes to many wetlands given increased temperature and changed rainfall and surface runoff and groundwater flows. The extent of change will determine the impact on wetlands with a decline in precipitation or an increase in evapotranspiration causing less-frequent flooding of existing wetlands but not necessarily the loss of wetlands. Increased precipitation would increase the length and depth of flooding of inland wetlands. Most susceptible are the many small wetlands, such as those in the prairie region that have very small watersheds and are located between the arid and the moist climate zones and which have seen extensive restoration given their importance for waterfowl breeding. Coastal wetlands may well be lost given limits on their ability to migrate inland, or adjacent salt marsh may be replaced by invading mangroves. The impact of hydrological change on the water regime and biogeochemical cycling in wetlands is likely to be large, but with uncertain outcomes, and affected also by multiple existing pressures. Changes in both boreal and tropical wetlands will affect the storage of carbon and release of carbon gases.

Europe (Čížková et al. 2013) and Russia (Robarts et al. 2013)

Annual precipitation is expected to increase in northern Europe especially in the winter months but decrease in most of southern Europe. Increased evapotranspiration may offset the increased water inputs. Summer drought is likely to be important for inland wetlands with the frequency and intensity most likely to increase from the north to the south. Sea level rise will likely have decisive outcomes for coastal wetlands especially along the Atlantic coast, with an expected increase in extreme sea level events along the continental North Sea coast. A generally wetter and warmer climate is expected for Russia with the highest increase in annual and winter mean precipitation in boreal Asia resulting in an increase in annual runoff in the major Siberian rivers. Annual precipitation is expected to increase the most in northern Russia with increases in both summer and winter. West Siberia is warming faster than the Arctic as a whole and it also contains the world's largest stores of peat with expected large increases in dissolved organic carbon in rivers and significant impacts on aquatic biogeochemical cycles and biological productivity.

South America (Junk 2013)

Temperature increases are expected to be greatest in the continental regions, including the central Amazon, but there is insufficient data or information about the effect on wetland species. It is expected that the species composition of many wetlands may change, but given the wide range of many species this is unlikely to result in mass extinctions. Temperate and boreal species may shift to higher latitudes and to higher altitudes in mountainous regions, and mangroves may move further to the north and south. However, while the species composition may change with increased temperature, the tropical and subtropical wetlands are expected to remain at the same locality as long as hydrological conditions are suitable. A major threat will be the increase of fires, especially in periodically flooded savannahs such as the Pantanal and the Araguaia River floodplain where flood adapted tree species are sensitive to fire. Further fires in the grassland that have resulted as a consequence of land clearing may extend the impact into adjacent wetlands. There are contradictory views on the effects on the Amazon rainforests, about one third of which is periodically flooded or waterlogged. There are predictions that the Amazon rain forest may change to a semi-deciduous forest with a dense network of evergreen riparian and floodplain forests. Accelerated melting of snow and ice, including from glaciers in Patagonia and in the Andes, will reduce the amount of water stored in these areas. Accelerated snowmelt in the Andes could change the wet-dry periodicity in large rivers with large changes in the discharge and flood pulses. Rising sea levels will affect coastal wetlands that in many areas have limited room to migrate given the extent of human infrastructure and development. The biota in the lower reaches of many large rivers will likely be affected by sea level rise and an extension of tidal movement upstream. Stronger El Nino and La Nina events will strongly affect the rainwater-fed floodplains and swamps.

Africa (Mitchell 2013)

Precipitation is projected to increase over the equatorial region of Africa, but in the mid-latitude regions, over the deserts, it is projected to decrease and result in less surface water being available. The Mediterranean coast of North Africa will become drier. A band running west to east, which includes parts of the Sahel and areas to the south of it, is predicted to have increasing water resources. Under a scenario of moderate climate change, severe future threats to both freshwater ecosystem functioning as well as water availability for humans may be expected, as for instance for south-western part of Africa, e.g., the Namib and Kalahari deserts. This will be exacerbated by the accompanying changes in the frequencies and magnitudes of floods and droughts. The eastern part of South Africa, particularly east of the escarpment, will receive increased precipitation while the western coast will become drier. But, there are considerable disagreements between the predictions of different models. It is possible that the resilience of many ecosystems may be exceeded this century by an unprecedented combination of climate change and associated disturbances, such as floods, drought, and other global change drivers like land-use change, pollution, fragmentation of natural systems, and overexploitation of resources. Another predicted effect of increasing temperature is that the distribution of tropical diseases such as malaria and bilharzia will change and include areas currently free of these diseases.

Asia (An et al. 2013; Gopal 2013)

The expected rise in temperature across Asia is expected to be greater in South and Central Asia than in Southeast Asia with warmer winters also occurring in the south. Temperature increases in the Himalaya will accelerate the melting of glaciers with changes to the water regimes of the rivers and associated wetlands. Precipitation from the monsoon is expected to increase annually but with more temporal and spatial variability, with fewer rainy days and higher intensity of extreme events. Heavy rainfall events are projected to increase in the western and eastern parts of south Asia, and summer precipitation to decline over the semi-arid western central Asia but increase in South and Southeast Asia. The impact of sea level rise is expected to have a major impact on the mangroves and coastal freshwater or brackish wetlands throughout the region, including those in the deltas of large rivers. Warming has also reduced the water-storage capacity of the Qinghai-Tibet Plateau with consequences for the flow of water into some of the major rivers of the world, including the Yangtze, Mekong, and Ganges. The loss of glaciers and wetlands in high altitude areas is expected to continue, but further changes in precipitation and water flows confounds efforts to predict what changes are likely.

Australia (Finlayson et al. 2013)

Rainfall is expected to decrease across many parts of the continent with more dry days but more intense storms when it does rain, including for tropical cyclones. Drought and evaporation rates are expected to increase, as is the frequency of fire. There is an expectation that across much of southern Australia it will be slightly warmer with lower and more variable rainfall. Such changes could exacerbate the extent of rainfall variability already experienced. Based on the experience of a recent decade long drought this could cause major changes in water flows and inundation of wetlands and affect the dispersal and breeding of many migratory or nomadic species. Prolonged drying of riverine and floodplain environments could lead to the development of acidic soils, as experienced during the drought years. The vulnerability of coastal wetlands in northern Australia to climate change and sea level rise has been assessed and is expected to result in substantive change to the biophysical character of the wetlands. Sea level rise, shoreline erosion, and saltwater intrusion could change both saline and freshwater wetlands and enable mangroves to invade coastal marshes. Coral reefs are at risk from further bleaching and acidification of the oceans.

Impact on Waterbirds

The general nature of the impacts of climate change on waterbirds is described below based on a summary provided by Finlayson et al. (2006) who noted that although some changes can be identified the exact extent, intensity, and time frames of such changes are difficult to predict. The most severe effects of climate change on waterbirds come about because of: (i) the loss and degradation of inter-tidal habitats; (ii) increased salinization of coastal freshwater wetlands; (iii) a reduction in the extent of wetlands and duration of flooding in arid and semi-arid areas; and (iv) the loss of wetland breeding habitats in the arctic and subarctic. Many of these changes are likely to occur relatively quickly as sea levels rise and temperatures increase.

The extent of loss and degradation of coastal wetlands and its effects on coastal waterbirds will depend on the ability of coastal environments to move inland as sea level rises. Where this is possible the area of inter-tidal wetlands might even expand; however, where coastal infrastructure is well established and where sea defenses are strengthened the area of inter-tidal habitats is likely to be reduced. Further, the length of time that the remaining inter-tidal areas are exposed during each tidal cycle may be reduced, affecting the time available for shorebirds to feed. The time shorebirds spend feeding during low tide varies between species and depends on their body size and ambient temperatures and increases when they are accumulating reserves prior to migration. As smaller species spend almost all of their time feeding they could potentially be the most seriously affected. Some inter-tidal areas will probably become unusable by the smaller species. Expected reductions in the metabolic rates of some species as a consequence of rising temperatures are unlikely to offset the loss of feeding time. Reduced feeding could also result in reduced survival during winter and during migration. Further, reduced body condition on arrival at the breeding grounds in the Arctic might reduce the breeding success of migratory species. Rising temperatures will also cause changes in the abundance and growth of the inter-tidal invertebrate populations that constitute the prey of shorebirds.

The effects of rising temperatures on plant communities in the Arctic may be substantial and, among other changes, lead to an expansion of boreal forest into current tundra areas that are important for breeding waterbirds, such as many goose species and a large proportion of calidrid sandpipers. While an increase in temperatures could increase productivity, which could potentially compensate to some extent for habitat loss, it may be offset by a likely increase in loss of nests and chicks to predation as predators, such as the red fox, expand their range. This example points to the complex ecological interactions that may occur and affect the survival of breeding populations in specific areas.

Climate change is also expected to result in changes to rainfall patterns, with some areas experiencing increases and others decreases or more intense events. Many currently dry areas, such as in parts of Australia, Asia, and Africa, may experience more rainfall variability and drier conditions. As many wetlands and waterbird populations in these areas are already highly stressed from habitat loss due to agriculture, including reduced water flows caused by water extraction for irrigation, pollution, and increasing salinization, these changes may exacerbate current pressures. This may impact on waterbird populations in drier environments that are characterized by unpredictable and relatively infrequent breeding, high adult survival, and high mobility. Successful breeding in such areas often requires exceptional flooding events that last long enough for completion of the breeding cycle. Reduced rainfall could increase the intervals between flooding events as well as shorten their duration. Reduced breeding success and recruitment should be expected as a first response to such changes, followed by reduced survival of adults and then widespread population declines. There will almost certainly be a great deal of regional variation, with some areas experiencing increases in waterbird populations and others, decreases, although the current concern has focused on the latter.

A recent analysis of 52 breeding migratory shorebird taxa in North America found that 45 were predicted to be more at risk of extinction when climate change was added to existing risks (Galbraith et al. 2014). The increased risk was due to loss of (i) breeding habitat; (ii) coastal and inland migration stopover habitats due to sea level rise and drought; and (iii) loss of coastal wintering habitat due to sea level rise. For migratory bird species, and in particular long-distance migrants, further effort is needed to determine: (i) the effects of habitat alteration at stopover points and wintering areas; (ii) the amounts and locations of major habitat types, as well as the carrying capacities of these habitats; (iii) the behavior, home range, and resource needs of species most likely to be vulnerable to global warming; and (iv) suitable policies and legislation at a continental scale, or better, at the flyway scale where possible to respond to adverse changes.

Adaptation

The IPCC has defined adaptation as "initiatives and measures to reduce the vulnerability of natural and human systems against actual or expected climate change effects" although others have extended this to also include the ability of a system to cope with environmental stress, including that from climate change. In this respect, adaptation fits comfortably with the Ramsar Convention's wise use approach that underpins global efforts to maintain or restore the ecological character of wetlands. Specifically, wise use of wetlands is defined as "the maintenance of their ecological character, achieved through the implementation of ecosystem approaches, within the context of sustainable development." (Finlayson et al. 2011).

While the convention provides guidance for the wise use of wetlands through the Wise Use Handbooks (Ramsar Secretariat 2010), it does not provide specific guidance on responding to the ecological consequences of climate change. In response to this situation, Finlayson et al. (2013) suggested areas where the convention could develop guidance applicable to climate change as part of its wise use approach, including: (i) assessing changes in the distribution of species and whether these constitute a change in the ecological character of the wetland; (ii) assessing the usefulness of models of wetland response to climate change; (iii) assessing the value in allocating water to protected sites where restoration would be contingent on reallocation of larger volumes of water; (iv) assessing the efficacy of engineering responses with the potential to deliver more water-efficient environmental outcomes for wetlands; and (v) determining if the description of the ecological character of a Ramsar site at the time of listing is a suitable reference for management purposes.

Other approaches to adaptation have considered the adequacy of current management approaches and assessed these to determine if they were appropriate under climate change or represented maladaptation. This approach takes advantage of existing knowledge and understanding of wetland management and places it within climate scenario as a way of ascertaining what may or may not be appropriate responses given local circumstances and opportunities. Lukasiewicz et al. (2013) investigated the potential of a number of existing management approaches, including the use of environmental flows and engineering works and measures, for adaptation and concluded that there were many activities underway that, if extended and linked, would comprise a substantial ecosystem-based approach to adaptation.

While adaptation measures have the potential to reduce the adverse effects of climate change it is unlikely that they can prevent all impacts. They can promote conservation and the sustainable use of biodiversity and reduce the impact of changes in climate and climatic extremes on biodiversity. Further, the effectiveness of adaptation activities can be enhanced when they are integrated within broader strategies designed to make development more sustainable, although the adoption of an ecosystem-based approach would likely be constrained by institutional complexity and socioeconomic issues.

United Nations Framework Convention on Climate Change (UNFCCC)

The UNFCCC is one of three intergovernmental conventions adopted at the Rio Earth Summit in 1992, along with the UN Convention on Biological Diversity and the Convention to Combat Desertification. It came into force on 21st March 1994 and now has 195 contracting parties. The general information on the convention that is presented below largely comes from the material presented on the website https://unfccc.int/2860.php.

The general purpose of the convention is to cooperatively consider what could be done to limit average global temperature increases and the resulting climate change and to cope with whatever impacts may occur. The ultimate aim is to prevent "dangerous" human interference with the climate system and to stabilize greenhouse gas concentrations "*... at a level that would prevent dangerous anthropogenic (human induced) interference with the climate system*" (https://unfccc.int/). The convention further anticipates that "*... such a level should be achieved within a time-frame sufficient to allow ecosystems to adapt naturally to climate change, to ensure that food production is not threatened, and to enable economic development to proceed in a sustainable manner.*"

The convention puts the responsibility on developed countries to lead the international effort to meet these aims, given that they have been responsible for most of the past and current greenhouse gas emissions and are therefore expected to do the most to cut emissions. This is, at times, a contentious issue given the increase in emissions from some developing countries. The developed countries are referred to as Annex I countries and belong to the Organization for Economic Cooperation and Development (OECD). They were expected by the year 2000 to reduce emissions to 1990 levels; some of them have succeeded. Developed countries have also agreed to support climate change activities in developing countries through financial assistance to address specific climate change actions and to share appropriate technology.

Annex 1 countries are required to report regularly on their climate change activities and policies, including the measures outlined under the Kyoto Protocol if they have formally accepted it. An inventory of their greenhouse gas emissions, including for 1990 (the baseline for this purpose) and all years since is required annually. The requirements on developing countries are less arduous with reports on their actions to: (i) mitigate climate change and (ii) adapt to the impacts. This reporting is contingent on obtaining funding to prepare the reports, especially for the least developed countries. The Kyoto Protocol is an agreement linked to the UNFCCC which commits the contracting parties to set and meet binding emission reduction targets (https://unfccc.int/kyoto_protocol/items/2830.php). The Protocol was adopted in December 1997 and came into force in February 2005 with detailed rules, known as the Marrakesh Accords, being agreed in 2001. The protocol places a heavier requirement on developed nations to reduce emissions under the principle of common but differentiated responsibilities, with the first commitment period from 2008 to 2012 and the second from 2013 to 2020. The first commitment period included 39 industrialized countries and the European Community that committed to reduce GHG emissions to an average of five percent against 1990 levels. The second period contains a commitment to reduce emissions by at least 18% below 1990 levels. Countries are expected to meet their targets mainly through national measures or through three market-based mechanisms, namely: international emissions trading; clean development mechanism; and joint implementation. Emissions have to be monitored and records kept of all emissions trading.

The convention emphasizes that all countries are vulnerable to the effects of climate change and calls for special efforts to ease the consequences, especially in developing countries. This led to the consideration of approaches for assessing the vulnerability of both socioeconomic and ecological systems to climate change, with the Ramsar Convention on Wetlands providing a method for assessing the vulnerability of wetlands to climate change (Gitay et al. 2011) and requesting further investigation of the socioeconomic vulnerabilities of communities dependent on wetlands for at least part of their livelihood. Further effort has also been afforded to adaptation to climate change, with an emphasis on observation, assessment of climate impacts and vulnerability, planning and implementation, and monitoring and evaluation of adaptation actions. Lukasiewicz et al. (2013) have highlighted that current management practices could enable adaptation to climate change, but under some conditions these could prove to be maladaptive.

The convention also requires contracting parties to mitigate climate change, reduce emissions, and enhance carbon sinks. A range of policies and practices has been introduced including the development of an international fund for Reducing Emissions from Deforestation and Forest Degradation (REDD+) in developing countries. It embraces policies and incentives for developing countries and includes the role of conservation, sustainable management of forests, and enhancement of forest carbon stocks in developing countries. It also has immense potential for encouraging the management and restoration of wetlands now that it has been expanded to include activities that improve ecosystem services and provide co-benefits to communities and biodiversity (Alexander et al. 2011).

Intergovernmental Panel on Climate Change (IPCC)

The Intergovernmental Panel on Climate Change (IPCC) was established in 1988 by the United Nations Environment Programme (UNEP) and the World Meteorological Organization (WMO) to provide a scientific assessment of knowledge about climate change and possible environmental and socioeconomic impacts. Later the same year, the General Assembly of the United Nations endorsed the establishment of the IPCC. The information that follows has been largely derived from the IPCC web pages (http://www.ipcc.ch/).

The IPCC is an intergovernmental body open to all member countries of the United Nations (UN) and WMO. There are currently 195 member countries. The purpose of the IPCC is to review and assess the most recent technical and socioeconomic information about the cause, extent, and consequences of climate change to support the formulation of realistic responses. It does not undertake research nor monitor changes in the climate. Governments participate in the review process and the plenary sessions where decisions are made about the work program and assessment reports. The plenary session also elects the IPCC Bureau Members, including the Chair. A Secretariat is hosted at the WMO in Geneva, coordinating the work of the IPCC and liaising with governments.

A large number of scientists voluntarily contribute to the assessments undertaken by the IPCC. These assessments are based on extensive reviews in order to ensure a complete and objective coverage of current information. The initial task given to the IPCC was the preparation of a comprehensive review and recommendations about "*. . .the state of knowledge of the science of climate change; the social and economic impact of climate change, and possible response strategies and elements for inclusion in a possible future international convention on climate.*" Today its role is "*. . .to assess on a comprehensive, objective, open and transparent basis the scientific, technical and socio-economic information relevant to understanding the scientific basis of risk of human-induced climate change, its potential impacts and options for adaptation and mitigation. IPCC reports should be neutral with respect to policy, although they may need to deal objectively with scientific, technical and socio-economic factors relevant to the application of particular policies.*"

The first IPCC Assessment Report in 1990 underlined the importance of climate change as a challenge requiring international cooperation to tackle its consequences. This played a key role in the formation of the United Nations Framework Convention on Climate Change (UNFCCC). Since then, the IPCC has delivered regular scientific reports about climate change produced worldwide. Five assessment reports have now been produced (http://www.ipcc.ch/publications_and_data/publications_and_data_reports.shtml#1):

First Assessment Report – FAR – 1990
Second Assessment Report – SAR – 1995
Third Assessment Report – TAR – 2001
Fourth Assessment Report – AR4 – 2007
Fifth Assessment Report – AR5 – 2013/14

Wetlands have been considered in the assessment reports with information spread across many chapters, including regional assessments and those addressing ecosystem services. The information on wetlands from the TAR was extracted and provided as a report to the Ramsar Convention's 7th conference of parties in 2002 in support of a formal resolution on climate change and wetlands (van Dam et al. 2002).

The IPCC also provides scientific and technical information to the UNFCCC, such as methodological reports and guidelines to help parties prepare national greenhouse gas inventories. In 2013, the IPCC produced a supplement to the 2006 Guidelines for National Greenhouse Gas Inventories (Hiraishi et al. 2014). The Second Assessment Report provided information that was used to support the adoption of the Kyoto Protocol in 1997. The protocol is an international agreement associated with the UNFCCC. It came into force in February 2005 and contains detailed rules, known as the Marrakesh Accords, for setting internationally binding emission reduction targets (https://unfccc.int/kyoto_protocol/items/2830.php).

The Ramsar Convention has participated in meetings of the IPCC and has a keen interest in the impact of climate change on wetlands and the potential contribution of wetlands to the mitigation of climate change. In addition to developing a method for assessing the vulnerability of wetlands to climate change, including the impacts of sea level rise, the convention has addressed adaptation to climate change through its wise use principles (Finlayson 2013) with a current interest in ecosystem-based adaptation which is compatible with wise use (Finlayson et al. 2011). It has further taken an interest in the potential of wetlands to sequester carbon to mitigate climate change, including in peatlands and coastal wetlands (Lloyd et al. 2013).

The IPCC and Albert Arnold (Al) Gore Jr. were awarded the Nobel Peace Prize "*...for their efforts to build up and disseminate greater knowledge about human-made climate change, and to lay the foundations for the measures that are needed to counteract such change*" (http://nobelpeaceprize.org/en_GB/laureates/laureates-2007/announce-2007/). By making the award, the Norwegian Nobel Committee sought to sharpen the focus on the decisions and mechanisms needed to reduce the threat of climate change and benefit humankind.

Reducing Emissions from Deforestation and Forest Degradation

75

Sasha Alexander

Contents

Abstract

Reducing emissions from deforestation and forest degradation (REDD) was first introduced in 2005 at the 11th meeting of the Conference of the Parties (COP11) of the UN Framework Convention on Climate Change (UNFCCC) in order to establish an international funding mechanism for reducing carbon emissions and protecting forest ecosystems. At that time, REDD was envisioned as a fund-based and/or market-based approach to assist the developing countries in meeting their emission obligations under the Clean Development Mechanism (CDM), where the contribution of conservation, afforestation, and reforestation (ecological restoration) to reducing emissions was first recognized. In 2007 (UNFCCC COP15), the Bali Action Plan was agreed to, and the REDD mechanism was expanded to include the sustainable management of forests and enhancement of forest carbon stocks and is now known as REDD+.

Background

Reducing emissions from deforestation and forest degradation (REDD) was first introduced in 2005 at the 11th meeting of the Conference of the Parties (COP11) of the UN Framework Convention on Climate Change (UNFCCC) in order to establish an international funding mechanism for reducing carbon emissions and protecting forest ecosystems. At that time, REDD was envisioned as a fund-based and/or market-based approach to assist the developing countries in meeting their emission obligations under the Clean Development Mechanism (CDM), where the contribution of conservation, afforestation, and reforestation (ecological restoration) to reducing emissions was first recognized.

The degradation and loss of terrestrial and wetland forests has become a significant challenge for natural resource management policies and strategies that aim to mitigate, and foster adaptation to, climate change impacts. The Intergovernmental Panel on Climate Change (IPCC) concluded that "reducing and/or preventing deforestation and preventing the release of carbon emissions into the atmosphere is the mitigation option with the largest and most immediate carbon stock impact in the short-term per hectare and per year globally" (Metz et al. 2007).

In 2007, at the UNFCCC COP15, the Bali Action Plan was agreed to, and the REDD mechanism was expanded to include the sustainable management of forests and enhancement of forest carbon stocks and is now known as REDD+ (or REDDplus). In response to the processes outlined in the Bali Action Plan, the UN-REDD Programme and the World Bank Forest Carbon Partnership Facility (FCPF) were established in 2008 to financially help the developing countries to build capacity, broaden stakeholder engagement, and provide overall support for their REDD+ readiness efforts.

The Cancun Agreements

In December 2010, at the UNFCCC COP17, the almost unanimous Cancun Agreements crystallized the previously negotiated REDD+ language which now embraces "policy approaches and positive incentives on issues relating to reducing emissions from deforestation and forest degradation in developing countries; and the role of conservation, sustainable management of forests and enhancement of forest carbon stocks in developing countries" (UNFCCC 2010). Bolivia's dissent in Cancun revolved around their opposition to using a market-based approach (carbon credits) to finance REDD+, thus delaying a final decision and continuing to rely on bilateral and multilateral funding until the UNFCCC COP18.

Furthermore, the Cancun Agreements include the creation of a Green Climate Fund and guidance/safeguards for potential REDD+ donors and recipients during the so-called "fast-start finance" period in preparation for the post-2012 climate change agreements. However, until the financing and monitoring (MRV) mechanisms have been agreed upon, all potential REDD+ projects will continue to remain outside the

UNFCCC. Although the primary goals of REDD+ are to reduce emissions and sequester carbon in forest ecosystems, the Cancun Agreements include activities that also provide multiple co-benefits to biodiversity, ecosystem functions, and local and indigenous communities (Dickson and Osti 2010).

Implications for Forested Wetlands

Forest conservation, management, and restoration can lead to reduced emissions and increased carbon sequestration; however the magnitude and timescale of the response varies by ecosystem type. The sustainable management of and enhancement of carbon stocks in forested wetlands (mangrove, peatland, and bottomland forests) are considered to make relatively large contributions to global emission reductions in the long term. Although these wetland ecosystems represent only a small percentage of the world's forests, they are some of the most productive in terms of carbon storage and other vital ecosystem services. This is largely a result of high aboveground biomass or standing carbon stocks and their capacity to store carbon belowground in soil and sediment.

For example, the average aboveground biomass in mangrove forests is 247.4 t ha^{-1} (similar to that of tropical terrestrial forests), while carbon burial averages 181.3 gC m^{-2} $year^{-1}$ or a total of 29.0 TgC $year^{-1}$ (Alongi 2009). This significant amount of long-term carbon storage suggests that REDD+ funding for conservation, management, and restoration activities in these forested wetland ecosystems could reduce emissions and increase global carbon storage, perhaps even more than upland forests on a per hectare basis (Laffoley and Grimsditch 2009). The tangible co-benefits of revitalized mangrove forests extend to local and indigenous communities that depend on their goods and services (e.g., timber, fisheries, water treatment, and storm/climate protection).

Future Challenges

It is important to recognize that, in practice, the multiple objectives of REDD+ (carbon, biodiversity, ecosystems, and communities) are not always synergistic or complementary and that, in fact, there are often significant and, some may argue, unnecessary trade-offs. The lack of good governance is perhaps the single greatest factor inhibiting these seemingly natural synergies or co-occurrences: government policy and regulation often segregate and skew outcomes by focusing on short-term benefits for a few, creating further inequity for many; social and consumer priorities when translated into action on the ground often fail to recognize the vital connection between biodiversity, ecosystem services, and sustainability; and the marginalization and limited land tenure rights of local and indigenous communities often tend to reduce stakeholder involvement and access to benefits (Skutsch and McCall 2010).

Measuring, **Reporting**, **and Verification** (**MRV**):In order to be eligible for funding, REDD+ activities will need to demonstrate cost-effectiveness, additionality (i.e., would be otherwise unfunded), and the capacity for, and verification of, long-term carbon sequestration. However, there are still a number of important unresolved issues related to carbon leakage, reporting, and verification. For example, a nation can opt out of reporting soil carbon emissions if it is determined that they are not substantial. Although MRV systems are currently being developed to provide the technical support needed to assist developing nations in designing and implementing REDD+ projects, there is a need for greater input on establishing parameters for carbon, biodiversity, ecosystem, and socioeconomic indicators.

Informal Forestry Sector and Subnational Integration: The informal forestry sector is one that evolves in response to scarce resources or seeks to operate outside regulations that often disfavor local and indigenous communities and incentivize unsustainable uses. The informal sector is usually community based and not subject to the same systematic private/public management found within the formal forestry sector (e.g., timber concessions, national parks, and other protected areas). An important challenge for forest restoration will be the inclusion of this sector in REDD+ national strategies or action plans so as to ensure effective stakeholder participation, the integration of traditional and community forestry management practices, and a commitment to low-emission rural development. In addition to the informal sector considerations, it is critical that subnational activities be recognized and effectively incorporated into these national strategies or action plans as many potential REDD+ activities are under the jurisdiction of local and state/provincial authorities.

Benefits to Local and Indigenous Communities: Yet another challenge to overcome is safeguarding the rights and land tenure of local and indigenous communities and acquiring their full participation, when appropriate, as key stakeholders in REDD+ activities. Local and indigenous communities are often the traditional stewards of forest-based ecosystem services that not only benefit them but the rest of the world. Policy approaches to, and positive incentives for, reducing emissions, like REDD+, will undoubtedly increase the value of local community and indigenous lands. Thus, clear tenure rights (land titling) would be a cost-effective component of REDD+ national strategies or action plans to reduce emissions and provide multiple co-benefits to biodiversity, ecosystems, and communities. One idea that seems to hold great potential for the equitable treatment and involvement of local and indigenous communities is that of nested governance whereby there is a hierarchy of decision-making processes and multi-sectoral coordination that accounts for REDD+ activities at all spatial scales, from the global to the local (Sikor et al. 2010).

Management and Sustainable Development of Wetlands

76

Robert J. McInnes

Contents

Abstract

Wetland management has over the past few decades shifted strongly toward a focus on ensuring the sustainable development of individual sites and suites of wetlands across landscapes. This considers the multiple uses of wetlands and the increasing demands for the ecosystem services they provide. The concept of sustainable development has a long history in both the development and environmental literature and can be considered as development that meets the needs of the present without compromising the ability of future generations to to meet their owns needs. The Ramsar Convention on Wetlands recognizes that the conservation and wise use of all wetlands contributes towards achieving sustainable development throughout the world. Therefore, sustainable development is at the heart of the global wise use of wetlands.

Introduction

Wetland management has over the past few decades shifted strongly toward a focus on ensuring the sustainable development of individual sites and suites of wetlands across landscapes. This considers the multiple uses of wetlands and the increasing demands for the ecosystem services they provide, as expressed through the Millennium Ecosystem Assessment (2005) and other publications. The concept of sustainable development has a long history in both the development and environmental literature. However, a key landmark was achieved in 1984, when the United Nations established an independent group of 22 people drawn from developing and developed member states in order to identify long-term environmental strategies for the global community. In 1987, the World Conference on Environment and Development published their report entitled "Our Common Future" (WCED 1987), often referred to as the "Brundtland Report," with respect to the chairperson, the then Norwegian Prime Minister, Gro Harlem Brundtland. The term "sustainable development" was widely used throughout the report and was defined as:

> Development that meets the needs of the present without compromising the ability of future generations to meet their own needs.

The report is commonly considered to represent a watershed in terms of environmental awareness and placed sustainable development into the political arena of international development thinking (Sneddon et al. 2006). Since publication, the report has been translated into more than 20 languages and, despite the fact that there are many different definitions emanating from various disciplines each with different assumptions about the basic relationship between society and nature, its definition of sustainable development continues to be widely used. This reflects a common understanding that humanity has the ability, understanding, and technology to make development sustainable to ensure that the needs of the present generation are met without compromising the ability of future generations to meet their own needs.

The concept of sustainable development implies that there are limitations imposed by the current knowledge, technology, and societal organization capabilities on environmental resources and the capacity of the biosphere to tolerate the negative impacts of human activities. But it has been argued as far back as Thomas Malthus (1872) that technology and social organization can be both managed and improved to facilitate progressive economic growth. However, today sustainable development is being pursued in an increasingly globalized world, which still exhibits a high degree of poverty (Chany and Gertz 2011) and increasing rates of environmental degradation and biodiversity decline (Butchart et al. 2010), including for wetlands (Davidson 2014; Gardner et al. 2015). The global challenge for sustainable development lies in understanding the complex and evolving interdependencies of environment, social and economic development, and the ability to understand the conceptual, contextual, and geopolitical dimensions in order to achieve the future perceived by the Brundtland Report. This is as important for wetlands as it is for other ecosystems especially given the high rates of wetland loss globally (Davidson 2014).

Sustainable Development Challenges

While numerous definitions of sustainable development exist, most encompass the idea that it is comprised of three interdependent pillars, namely, ecological, economic, and social. (In many cases the words ecological and environmental are used interchangeably, although the latter can also be used to encompass ecological, social, and economic components.) The differences and nuances contained in definitions used by different sectors of society are important as they can indicate differences in the way that sustainability is viewed and the means for achieving sustainable development. Difficulties can arise as sustainable development, and *sustainability* are complex and multidimensional concepts, which often seeks to combine efficiency and equity based on social, economic, and environmental elements (Ciegis et al. 2015). These differences can become increasingly important when transferred to the policy development arena. Even the seemingly simple definition in the Brundtland Report, which separates the needs of present and future generations, implies that future needs are known and that any limits that are applied today will meet the demands of tomorrow. Similarly, "needs" may mean many different things to different societies and people, and some future needs may remain unknown. Therefore, ambiguities emerge in terms of the legacy that one generation should leave for its progeny. Often this is considered in terms of natural capital, but it may also embrace cultural, technological, or social elements.

Setting Global Targets for Sustainable Development

The United Nations Conference on Environment and Development, the "Earth Summit," which took place in Rio de Janeiro, Brazil in 1992, marked a significant moment in the course of sustainable development. One of the central aims was to identify the principles of an agenda for future action toward sustainable development with, for the first time, consideration of environmental sustainability and specifically biodiversity. However, tensions were in evidence between developed and developing countries and the different needs for exploitation of resources in order to deliver economic benefits. However, the post-Rio development of international treaties, such as the Convention on Biological Diversity (CBD) and the United Nations Framework Convention on Climate Change (UNFCCC), brought with them the positive ambition to foster the coordination of markets and public policies at the global level while maintaining a commitment to sovereignty in order to deliver a more sustainable future.

In September 2000, to mark the new millennium, 147 heads of state met at the United Nations Headquarters to consider global social and environmental priorities. To elucidate their ambitions and to evaluate progress, a set of numerical targets and deadlines were established. These were called the Millennium Development Goals

(MDGs) (http://www.un.org/millenniumgoals/). All United Nations member states at the time, and a variety of international organizations, committed to help achieve the following MDGs by 2015:

1. To eradicate extreme poverty and hunger
2. To achieve universal primary education
3. To promote gender equality
4. To reduce child mortality
5. To improve maternal health
6. To combat HIV/AIDS, malaria, and other diseases
7. To ensure environmental sustainability
8. To develop a global partnership for development

Each goal was given specific targets and deadlines. Target 7 was divided into the following four components which captured elements of sustainable development including integrating the principles of sustainable development into country policies and programs and reversing the loss of environmental resources and reducing biodiversity loss by 2010 in order to achieve a significant reduction in the rate of loss.

- Target 7.A: Integrate the principles of sustainable development into country policies and programs and reverse the loss of environmental resources.
- Target 7.B: Reduce biodiversity loss, achieving, by 2010, a significant reduction in the rate of loss.
- Target 7.C: Halve, by 2015, the proportion of the population without sustainable access to safe drinking water and basic sanitation.
- Target 7.D: Achieve, by 2020, a significant improvement in the lives of at least 100 million slum dwellers.

In the report on progress toward the MDGs published 1 year before the achievement is due (United Nations 2014), there were some alarming failures with regard to delivery on sustainable development objectives described in Target 7. For instance, emissions of carbon dioxide (CO_2) were observed to continue to rise globally, water scarcity perpetuated in Northern Africa and parts of Western Asia, and starkly the report stated that overall, species populations were declining and distributions retracting and, hence, some were moving faster toward extinction (Ibid.). Of all the earth's ecosystems and species they support, the overall picture was most bleak for wetlands (Butchart et al. 2010). Consequently, question marks are raised regarding the ability of the global community to fully commit to achieving sustainable development and to integrate commitments under different treaties and obligations. A criticism made of implementation of the MGDs in Latin America and the Caribbean suggested that the 2010 Biodiversity Target represented a conservation goal that did not integrate wider sustainable development requirements, and while it catalyzed increased cooperation in the biodiversity cluster of multilateral environmental agreements, it failed to align policies and implementation activities around the CBD's sustainability principles (Gomar 2014).

In June 2012, 20 years after the "Earth Summit," world leaders, along with representatives from the private sectors and nongovernmental organizations came together to discuss "the future we want" at the Rio+20 United Nations Conference on Sustainable Development. The discussions focused on two main themes: how to build a green economy in order to deliver on sustainable development while lifting people out of poverty and how to improve global coordination for sustainable development. Through the outcome document "The Future We Want," the conference set out the mandate to develop the successors to the MDGs, which expire at the end of 2015, termed the Sustainable Development Goals (SDGs).

The United Nations published the zero order draft of the proposed SDGs in June 2015 (https://sustainabledevelopment.un.org/content/documents/7261Post-2015%20Summit%20-%202%20June%202015.pdf). The SDGs are an agenda for people, planet, and prosperity that seek to strengthen universal peace and shift the world on to a sustainable path. The agenda defines a sustainable future where the planet is protected and natural resources, including wetlands, are used sustainably. The zero order draft document acknowledges the progress made through the MDGs but accepts that progress has been uneven and some goals were not achieved. Therefore at the heart of the SDGs is the desire to finish what the MDGs failed to complete.

World leaders have pledged common action and endeavor across a broad policy agenda which has been captured in 17 goals (below) and 169 associated targets in an ambition to achieve a path toward sustainable development. The SDGs will come into effect on 1 January 2016 and will guide decision-making over the ensuing 15 years. The SDGs, along with the associated targets, are intended to be integrated and indivisible, global in nature and universally applicable. They take into account the realities of different national circumstances, capacities, and levels of development and also pay respect to sovereign policies and priorities. Targets are defined as aspirational and global, and it is the responsibility of each government to establish its own national targets based on the overarching global level of ambition.

- **Goal 1**. End poverty in all its forms everywhere.
- **Goal 2**. End hunger, achieve food security and improved nutrition, and promote sustainable agriculture.
- **Goal 3**. Ensure healthy lives and promote well-being for all at all ages.
- **Goal 4**. Ensure inclusive and equitable quality education and promote lifelong learning opportunities for all.
- **Goal 5**. Achieve gender equality and empower all women and girls.
- **Goal 6**. Ensure availability and sustainable management of water and sanitation for all.
- **Goal 7**. Ensure access to affordable, reliable, sustainable, and modern energy for all.
- **Goal 8**. Promote sustained, inclusive, and sustainable economic growth, full and productive employment, and decent work for all.
- **Goal 9**. Build resilient infrastructure, promote inclusive and sustainable industrialization, and foster innovation.
- **Goal 10**. Reduce inequality within and among countries.

- **Goal 11**. Make cities and human settlements inclusive, safe, resilient, and sustainable.
- **Goal 12**. Ensure sustainable consumption and production patterns.
- **Goal 13**. Take urgent action to combat climate change and its impacts.
- **Goal 14**. Conserve and sustainably use the oceans, seas, and marine resources for sustainable development.
- **Goal 15**. Protect, restore, and promote sustainable use of terrestrial ecosystems, sustainably manage forests, combat desertification, and halt and reverse land degradation and halt biodiversity loss.
- **Goal 16**. Promote peaceful and inclusive societies for sustainable development, provide access to justice for all, and build effective, accountable, and inclusive institutions at all levels.
- **Goal 17**. Strengthen the means of implementation and revitalize the global partnership for sustainable development.

Unlike the MDGs, wetlands have a high profile within the SDGs. Goal 6 seeks to ensure availability and sustainable management of water and sanitation for all. Within the goal there is a clear acknowledgment to protect and restore water-related ecosystems which include wetlands. Similarly, within Goal 15, which seeks to protect, restore, and promote sustainable use of terrestrial ecosystems, sustainably manage forests, combat desertification, and halt and reverse land degradation and halt biodiversity loss, the need to conserve, restore, and sustainably use wetlands in line with obligations under international agreements, such as the Ramsar Convention on Wetlands, is clearly stated. Therefore, information on the management of wetlands will be crucial for the ongoing reporting and evaluation of the delivery against the objectives of the SDGs. Further, information on the implementation of commitments under international agreements will also be needed, noting that Finlayson (2012) reported that with a few exceptions implementation of commitments under the Ramsar Convention had been inadequate.

Wise Use of Wetlands and Sustainable Development

The Ramsar Convention on Wetlands has adopted as its mission: "the conservation and wise use of all wetlands through local and national actions and international cooperation, as a contribution towards achieving sustainable development throughout the world" (http://www.ramsar.org/about/the-ramsar-convention-and-its-mission). Therefore, sustainable development is at the heart of the global wise use of wetlands. This commitment has been further endorsed through declarations and resolutions.

"Wise use" can be considered as the longest established intergovernmental example of an approach to conservation and sustainable development (Finlayson et al. 2011). The wise use concept was first defined by the Third Conference of the Parties to the Ramsar Convention (COP3, held in Regina, Canada, 1987) as "their sustainable utilization for the benefit of humankind in a way compatible with the maintenance of the natural properties of the ecosystem." It further defined "sustainable utilization" as "human use of a wetland so that it may yield the greatest continuous benefit to present generations while maintaining its potential to meet the needs and aspirations of future generations" (Ramsar Convention 1987). This was very similar to the definition adopted by the Brundtland Report published in the same year.

At the Ninth Conference of the Parties to the Ramsar Convention (COP9, held in Kampala, Uganda, 2005), further efforts were made to harmonize various terms in use by the Convention, including "wise use" and "ecological character" to take into account more widely used terms and definitions relating to ecosystems and sustainable development. The result was the following updated definition of wise use:

> Wise use of wetlands is the maintenance of their ecological character, achieved through the implementation of ecosystem approaches, within the context of sustainable development.

This definition considered ecosystem approaches – such as the one adopted by the Convention on Biological Diversity which states that the ecosystem approach is a strategy for the integrated management of land, water, and living resources that promotes conservation and sustainable use in an equitable way – as a basis for conservation and sustainable development of natural resources. The definition also placed such an approach "within the context of sustainable development" with the intention of recognizing that development could be facilitated in sustainable ways but that it should not imply that development is, or will be, the objective for every wetland.

To assist countries to manage their wetlands, the Ramsar Convention has produced a substantial amount of guidance for the wise use of all wetlands. Much of this has been presented in the Ramsar Handbooks for the Wise Use of Wetlands (Ramsar Convention Secretariat 2010) as well as Ramsar Technical Reports and Briefing Notes (Table 1). Further information is available in resolutions adopted by the 11th and 12th Conferences of Ramsar Contracting Parties (COP11 2012; COP12 2015) (see www.ramsar.org).

The linkages between the wise use and the sustainable development of wetlands were strengthened at the Global Forum on Wetlands for the Future, which was held in Tehran, Islamic Republic of Iran, in March 2011 to commemorate the 40th anniversary of the signing of the Ramsar Convention on Wetlands. The forum was attended by ministers, senior officials, and high-level representatives from contracting parties, international and regional organizations, academic institutions, and other partners to the Convention. A significant outcome of the forum was the "Tehran Declaration on Wetlands and Sustainable Development" (http://www.ramsar.org/sites/default/files/documents/pdf/ramsar_40/Tehran_Declaration%202011.pdf) which reiterated the linkages between the wise use of wetlands and sustainable development and called for the contents of the declaration to be conveyed to the World Summit on Sustainable Development.

Future Challenges

After 40 years of countries implementing the Convention, Finlayson et al. (2011) posed and then answered the question "has Ramsar's wise use approach helped achieve sustainable development for wetlands?" To relate this back to the Brundtland definition, the question could be rephrased as has development taken place in a manner as not to compromise the ability of wetlands to allow future generations to meet their own needs. Drawing on conclusions presented in the Millennium Ecosystem Assessment (2005), which reported that the degradation and loss of wetlands is more rapid than for other ecosystems and the status of both freshwater and coastal wetland species is deteriorating faster than those of other systems, the answer was that overall it seemed that this approach had not helped achieve sustainable development for wetlands. This position appears to have been substantiated by similar work on both species decline (Butchart et al. 2010) and estimates on the rate and extent of wetland loss (Davidson 2014). Finlayson et al. (2011) did add that without the efforts under the Convention that the situation may have been worse, as shown through the successful development of the list of Ramsar wetlands of international importance.

As the global store of wetlands decreases, the needs of future generations continue to be eroded. Therefore, the pressure on those responsible for implementing the SDGs to genuinely protect, restore, and promote sustainable use of ecosystems is greater than ever. Wetlands have been explicitly highlighted within the SDGs, giving them a higher profile than in the MDGs, which hopefully will keep the protection and restoration of wetlands on the global agenda and ultimately deliver sustainable development and the wise use of wetlands.

Abstract

The concept of sustainable development has been embedded in development and environmental thinking for several decades. In 2000 the world's leaders established the Millennium Development Goals (MDGs) as a collective agenda to improve the lives of people across the globe. In 2015 the Sustainable Development Goals (SDGs) were proposed, as the successors to the MDGs, representing an agenda for people, planet, and prosperity that seek to strengthen universal peace and shift the world on to a sustainable path.

Keywords

Sustainable development · Intergovernmental cooperation

Introduction

The concept of sustainable development has a long history in both the development and environmental literature. However, there have been several key landmarks over the last 30 years or so. One of the first milestones occurred in 1987 when the World Conference on Environment and Development published their report entitled, "Our Common Future" (WCED 1987), commonly termed the "Brundtland Report," after the chairperson, the then Norwegian Prime Minister, Gro Harlem Brundtland. The term "sustainable development" was widely used throughout the report and was defined as:

> Development that meets the needs of the present without compromising the ability of future generations to meet their own needs.

This definition has shaped considerably the thinking on sustainable development and has been very influential in directing global efforts to secure a sustainable future for all. The concept of sustainable development recognizes that there are limitations imposed on the capacity of the biosphere to tolerate the negative impacts of human activities by the current knowledge, technology, and societal organization capabilities. The current global challenge for sustainable development lies in understanding the complex and evolving interdependencies of environment, social and economic development within an increasingly globalized world, as shown through the analyses undertaken in the Millennium Ecosystem Assessment (2005).

The Millennium Development Goals: Precursors to the Sustainable Development Goals

The United Nations Conference on Environment and Development, known colloquially as the "Earth Summit," took place in Rio de Janeiro, Brazil, in 1992 and marked a significant moment in the history of sustainable development. One of the central aims was to identify the principles of an agenda for action towards sustainable development in the future which for the first time considered the environment and specifically biodiversity. Some 8 years late in September 2000, to mark the new millennium, heads of state met at the United Nations headquarters to review progress on the Earth Summit and consider a way forward in order to deliver a more sustainable future. The meeting adopted the Millennium Declaration which established the Millennium Development Goals (MDGs) which aimed to improve the lives of people around the world and included specific targets to be met by 2015. The MDGs cut across a variety of issues and were to germane to wetland management at many levels including through food production, hunger and poverty eradication, climate change adaptation and mitigation, water extraction, sanitation, and water-borne and vectored disease.

In the report on progress towards the MDGs published 1 year before achievement is due (United Nations 2014) there were some significant failures with regard to delivery. It is clear that some MDGs will meet their objectives by 2015, others will be within reach, while some will remain as urgent priorities for global leaders, in need of attention beyond 2015. It has been argued that progress of the MDGs has been limited by system-level constraints, including poor governance, weak institutions, and a lack of appropriately trained personnel (Horwitz et al. 2014).

In June 2012, 20 years after the “Earth Summit”, world leaders, along with representatives from the private sectors and nongovernmental organizations came together to discuss “the future we want” at the Rio + 20 United Nations Conference on Sustainable Development. The discussions focussed on two main themes: how to build a green economy in order to deliver on sustainable development while lifting people out of poverty and how to improve global co-ordination for sustainable development. Through the outcome document “The Future We Want” the conference set out the mandate to develop the successors to the MDGs, which expire at the end of 2015, termed the Sustainable Development Goals (SDGs).

The aspirations of the above-mentioned initiatives have been paraphrased by McCartney et al. (2014) in terms of seeking a balance between development and the sustainable use of ecosystem services as follows: “The key to sustainable development is achieving a balance between the exploitation of natural resources for economic development and conserving ecosystem services that are critical to everyone’s wellbeing and livelihoods. There is no blueprint for obtaining this balance but it is essential to understand how ecosystem services contribute to livelihoods and who benefits and who loses from changes arising from development interventions.” The further reiterated that the findings from the Millennium Ecosystem Assessment (2005) that emphasized the importance of adopting ecosystem-based approaches to wetland management that enabled communities to consider the trade-offs between different wetland ecosystem services as mechanisms for supporting the MDGs were as relevant for designing the SDGs.

The SDGs and Wetland Management

The United Nations published the zero order draft of the proposed SDGs in June 2015 (https://sustainabledevelopment.un.org/content/documents/7261Post-2015%20Summit%20-%202%20June%202015.pdf). The SDGs are an agenda for people, planet, and prosperity that seek to strengthen universal peace and shift the world on to a sustainable path. The agenda defines a sustainable future where the planet is protected and natural resources, including wetlands, are used sustainably. The “zero draft” document acknowledges the progress made through the MDGs but accepts that progress has been uneven and some goals were not achieved. Therefore, at the heart of the SDGs is the desire to complete what the MDGs failed to finish.

World leaders have pledged common action and endeavour across a broad policy agenda which has been captured in 17 Goals (below) and 169 associated targets in an ambition to achieve a path towards sustainable development (https://sustainabledevelopment.un.org/topics/sustainabledevelopmentgoals). The SDGs will come into effect on 1 January 2016 and will guide decision-making over the ensuing 15 years.

The SDGs, along with the associated targets, are intended to be integrated and indivisible, global in nature, and universally applicable. They take into account the realities of different national circumstances, capacities, and levels of development and also pay respect to sovereign policies and priorities. Targets are defined as aspirational and global, and it is the responsibility of each government to establish its own national targets based on the overarching global level of ambition.

- **Goal 1.** End poverty in all its forms everywhere
- **Goal 2.** End hunger, achieve food security and improved nutrition, and promote sustainable agriculture
- **Goal 3.** Ensure healthy lives and promote wellbeing for all at all ages
- **Goal 4.** Ensure inclusive and equitable quality education and promote lifelong learning opportunities for all
- **Goal 5.** Achieve gender equality and empower all women and girls
- **Goal 6.** Ensure availability and sustainable management of water and sanitation for all
- **Goal 7.** Ensure access to affordable, reliable, sustainable, and modern energy for all
- **Goal 8.** Promote sustained, inclusive, and sustainable economic growth, full and productive employment, and decent work for all
- **Goal 9.** Build resilient infrastructure, promote inclusive and sustainable industrialization, and foster innovation
- **Goal 10.** Reduce inequality within and among countries
- **Goal 11.** Make cities and human settlements inclusive, safe, resilient, and sustainable
- **Goal 12.** Ensure sustainable consumption and production patterns
- **Goal 13.** Take urgent action to combat climate change and its impacts
- **Goal 14.** Conserve and sustainably use the oceans, seas, and marine resources for sustainable development
- **Goal 15.** Protect, restore, and promote sustainable use of terrestrial ecosystems, sustainably manage forests, combat desertification, and halt and reverse land degradation and halt biodiversity loss
- **Goal 16.** Promote peaceful and inclusive societies for sustainable development, provide access to justice for all and build effective, accountable and inclusive institutions at all levels
- **Goal 17.** Strengthen the means of implementation and revitalize the global partnership for sustainable development

Wetland managers and policy-makers can contribute to the delivery of SDGs through the close links to a range of wetland issues including *inter alia* human health and disease, the provision of food, water and sanitation, the ability of wetlands to mitigate pollution, the wise use of urban wetlands as important natural infrastructure and the increased resilience of human communities to hazards. Unlike the MDGs, wetlands have a high and specific profile within the SDGs. Goal 6 seeks to ensure availability and sustainable management of water and sanitation for all and has the specific target of protecting and restoring water-related ecosystems, including mountains, forests, wetlands, rivers, aquifers, and lakes by 2020.

Similarly, within Goal 15, which seeks to protect, restore, and promote sustainable use of terrestrial ecosystems, sustainably manage forests, combat desertification, and halt and reverse land degradation and halt biodiversity loss, wetlands receive a specific mention in the targets. Target 15.1 states that by 2020, ensure the conservation, restoration, and sustainable use of terrestrial and inland freshwater ecosystems and their services, in particular forests, wetlands, mountains, and drylands, in line with obligations under international agreements. Therefore, the need to conserve, restore, and sustainably use wetlands in line with obligations under international agreements, such as the Ramsar Convention on Wetlands, is clear.

Future Challenges

Information on the management of wetlands will be crucial for the ongoing reporting and evaluation of delivery against the objectives of the SDGs. There will be an onus on wetland managers, from the site level, up to the intergovernmental level through the Ramsar Convention to play their part. In the recently adopted Ramsar Strategic Plan 2016–2024 (Ramsar Convention 2015), it is recognized that all wetlands including the Ramsar Site network will have a direct relevance to the achievement of the SDGs and especially those related to poverty eradication, food and nutrition, healthy living, gender equality, water quality and supply, water security, energy supply, reduction of natural disasters, innovation and the development of appropriate infrastructure, sustainable human settlements adaptation to climate change, oceans, seas and marine resources, biodiversity, and sustainable use of ecosystems.

The challenge in meeting the multiplicity of goals outlined through the SDGs has previously been expressed in many publications, as summarized in global assessments (MEA 2005; Molden et al. 2007) and expressed by Falkenmark et al. (2007) when considering how to avoid the costs of going too far when addressing the balances and trade-offs between agriculture, water, and ecosystems. This could be done by reconsidering the web of relationships that occur between people and wetlands through the medium of ecosystem services and by adopting the “settings” approach (Horwitz and Finlayson 2011), wherein wetlands are a setting for achieving the SDGs with commensurate benefits for people. In this manner, the many benefits that accrue for people through maintaining healthy wetlands can be assessed and trade-offs identified and agreed within the relevant socio-political landscape.

Abstract

This short paper outlines how intervening in the disruption to wetland ecosystem services will improve human health and help address the Millenium Development Goals. It also discusses systemic consequences, where addressing the MDGs (principally by the interventions imposed by other sectors) will need to be aware of the relationship between human health and wetland ecosystem health.

Introduction

Through the adoption by the United Nations in 2000 of the *Millennium Declaration,* the world's governments established the Millennium Development Goals (MDGs) to improve the lives of people around the world, particularly those most vulnerable and disadvantaged, with specific targets to be reached by 2015.

The MDGs are designed to lift people out of poverty, save lives, ensure adequate childhood education, reduce maternal deaths, and expand opportunities for women and girls through empowerment. Of direct relevance to wetlands and water resource management, they seek to ensure access to clean water and alleviate the burden of deadly and debilitating diseases that many people face. They seek to promote sustainable development and protect the most vulnerable from the devastating effects of multiple crises, whether they be conflicts, natural disasters, or volatility in prices for food and energy (United Nations 2012).

Beyond Sectoralism

Global attempts to achieve these goals and targets have not abated in the second half of the 15-year period: "At the 2010 High-level Plenary Meeting of the General Assembly on the Millennium Development Goals, world leaders reaffirmed their commitment to the MDGs and called for intensified collective action and the expansion of successful approaches" (United Nations 2011, p. 5). Along with this reaffirmation came a concerted effort to look beyond the sectoral boundaries that defined each of the goals. In particular, the "environmental" or "natural resource" sectors recognized that they had a contribution to make to each of the MDGs beyond just Goal 7 that sought to ensure environmental sustainability.

Early efforts to go beyond Goal 7 included UN WWDR (2006), Molden (2007), UNEP (2007), global reports that sought to place water management, agriculture, and global state of the environment reporting in the context of vulnerable peoples, and governance for sustainability. Attentiveness to the links and interplays between biodiversity and poverty and between human health and ecosystem services (Secretariat of the CBD 2010; Horwitz et al. 2012; Pretty et al. 2011) has demonstrated that the complex and "wicked" problems of both ecosystem change, and poverty must be addressed through intersectoral action. This is because many of the social, economic, and demographic driving forces, and possible response options, lie primarily outside the direct control of any one sector, like the environmental sector or the health sector. Instead they are embedded as attitudes, perceptions, and realities in sectors such as sanitation and water supply, education, energy, agriculture, trade, tourism, transport, development, and housing (Horwitz et al. 2015).

Table 1 Ways in which wise use and wetland management can contribute toward the achievement of the Millennium Development Goals (Modified from Horwitz et al. (Ramsar Technical Report No. 6, 2012), which was compiled using the material presented in Molden (2007), UNEP (2007), UN WWDR (2006), and as otherwise indicated)

Millennium Development Goals (MDGs)	How will intervening in disruption to wetland ecosystem services improve human health and help address the MDGs?	Systemic consequences: where will addressing MDGs need to be aware of the relationship between human health and wetland health?
1. Eradicate extreme poverty and hunger	Food security of the poor often depends on healthy ecosystems and the diversity of goods and ecological services they provide. Diverse wetland ecosystems are self-sustaining and provide the essential genetic material for aquaculture and horticulture. Sustainable livelihoods by definition seek to ensure that the core requirements of food and water are provided to those dependent on the provisioning of wetland ecosystems	The challenge for irrigated agriculture is to improve equity, reduce environmental damage, increase ecosystem services, and enhance water and land productivity in existing and new irrigated systems. Improving productivity should not be at the expense of other ecosystem services. If it is, the human, animal, and plant health consequences of ecosystem disruption will occur in full or in part due to a range of both direct and indirect impacts, the latter as a result of altered health status of livestock and wildlife
2. Achieve universal primary education	Wetland management needs to address the disruptions to ecosystem services that result in water-related diseases. Water-related diseases such as diarrheal infections cost about 443 million school days each year, diminish learning potential, and reduce the coping capacity of local populations for current predicaments and future ecosystem changes	Primary education should include knowledge of health, water, and energy issues at least (a fundamental necessity for urban dwellers who have become more alienated from their surroundings than at any stage in history). Education services can have tendencies to resist increases in attention to such environmental issues at the expense of other subjects
3. Promote gender equality and empower women	Addressing degradation in wetlands, such as water contamination and deforestation, will contribute to the health of women and girls. Women and girls bear the brunt of collecting water and fuelwood and are more vulnerable members of populations to waterborne diseases	Improved wetland management should involve women and girls in a meaningful way, perhaps by recognizing that women can play greater roles in wetland management than they currently do. "Wetland managers," as professions, tend to be dominated by men. Decision-making structures for water resource management, wetland management, and agriculture are also gendered in many parts of the world. These may operate as barriers to achieve this goal

(*continued*)

Table 1 (continued)

Millennium Development Goals (MDGs)	How will intervening in disruption to wetland ecosystem services improve human health and help address the MDGs?	Systemic consequences: where will addressing MDGs need to be aware of the relationship between human health and wetland health?
4. Reduce child mortality	Wetland management will become an essential operational requirement to reduce exposures to waterborne diseases, such as diarrhea and cholera. Prevalence of these diseases is a result of disruption of regulatory services (as a result of overextraction and inappropriate practices)	Interventions such as water treatment facilities (often through aid provision) will usually be technological and infrastructural in the short term to address immediate needs. However, the medium- to long-term goal should be the management of wetland ecosystems to ensure that they can provide suitable water purification and pathogen removal services
5. Improve maternal health	Addressing disruptions to wetland ecosystem services will always include an examination of water quality. Provision of clean water reduces the incidence of diseases that undermine maternal health and contribute to maternal morbidity and mortality	Improving the quality of source water from catchments, reservoirs, and wetlands in general, and distribution infrastructure, may reduce disinfection loads and the likelihood of maternal exposures to these loads
6. Combat major diseases	Up to 20% of the burden of disease in developing countries may be associated with environmental risk factors. Preventive environmental health measures are as important and at times more cost-effective than health treatment. Managing wetlands to enhance ecosystem services with the aim of reducing the likelihood of human exposures to pollutants and infectious diseases is preventive, attending to upstream environmental determinants of health. New biodiversity-derived medicines hold promises for fighting major diseases	Increasing human population sizes as a consequence of successful disease prevention measures may also increase pressure on local water and wetland resources. Wetland management needs to act in concert with water resource management to deal with these foreseeable consequences, for instance, by increasing awareness and thus changing behavior and by incorporating the concept of ecosystem services in prevention strategies. This management needs to be integrated with regional population policies, domestic livestock and wildlife policies (to reduce risk of emerging zoonoses), education, and awareness
7. Ensure environmental sustainability	Current trends in environmental degradation need to be reversed in order to sustain the health and productivity of the world's ecosystems. Wetlands, and the biodiversity they support, encompass many of the key ecosystems of the world and many	Development strategies that aim to safeguard the full range of benefits provided by wetlands might better achieve the goal while minimizing harm to wetlands. This requires recognizing the trade-offs that exist when managing for some ecosystem services like those concerned with

	of the most productive ones. Wetland management applies directly to this goal	production while trading off supporting and regulating services
8. Develop a global partnership for development	Poor countries are forced to exploit their natural resources, like wetland ecosystems, to generate revenue and make huge debt repayments. Unfair globalization practices export their harmful side effects to countries that often do not have effective governance regimes	Trade, tourism, and migrations of species are often transcontinental. Meaningful wetland management acknowledges that pests and pathogens capable of decreasing ecosystem services and having consequences for the health of local human, domestic, and wildlife communities can be distributed by inappropriately planned and controlled human activities. This needs appropriate recognition in global partnerships for development

Wetland Management and the MDGs

Wetland policy-makers and managers can make a contribution toward the MDGs wherever the close relationships between wetland management and food production, hunger and poverty, climate change, water extraction and use, and waterborne and aquatic vector-borne diseases are present. Contributions can be foreseen along two axes. The first is intervening in the ongoing disruption to wetland ecosystem services so as to help to improve human, domestic, and wildlife health and thereby address the MDGs; this axis is shown in column two of Table 1.

The second axis is shown in column three of Table 1. Methods for seeking to achieve the MDGs, improve human health, and enhance wetland ecosystem services may not necessarily be mutually beneficial – indeed, systemic effects like cross scale interactions and feedback consequences may prove to undermine the originally intended objectives. The activities to address MDGs by the international community, national actions, and actions by sectors other than wetland management need to be more cognizant of the systemic nature of the relationship between these objectives and wetland ecosystem health. Where potential negative consequences are foreseeable, this is no reason to avoid actions that seek to achieve these MDGs; rather, those consequences need to be understood and considered in decision-making.

An understanding of the trade-offs among different wetland ecosystem services and the need for cooperation across sectors is critical in designing further actions in support of the MDGs. For example, it is not uncommon for strategies intended to increase food production and reduce poverty to propose the conversion of marshes to agriculture, conversion of mangroves to aquaculture, and significant increases in the use of fertilizers to increase crop production. This approach, however, will reduce habitat area (and hence the magnitude of services provided by the original habitat), increase the input of water pollutants, remove the natural water filtering service provided by wetlands, and remove ecosystem services, such as storm surge protection, timber and charcoal supply, and fish habitat provided by mangroves, on which local residents in particular rely. This will make the development goal of improved water and sanitation more difficult to achieve and may in fact increase poverty for some groups. In contrast, a development strategy that safeguards the full range of benefits provided by wetlands might better achieve the set of development goals while minimizing future harm to the wetlands.

The Future: MDGs and Their Next Iteration

Some MDGs will be achieved in 2015, others will be within reach, others will remain as urgent priorities for global leaders; indeed attention will be needed beyond 2015. In the meantime, other urgent priorities have emerged. An evaluation of the achievements of the MDGs should examine the degree to which local communities have been involved in decision-making regarding interventions, "atypical" allegiances have been formed, and trust and reciprocity with local communities, across sectors, and across disciplines have been developed. Arguably, progress on MDGs has been limited by system-level constraints, including poor governance, weak institutions, and a lack of appropriately trained personnel. Wetland managers, indeed the wetland sector, will need to be (more) active and participate in the evaluation of the MDGs and the next iteration in order to make the sorts of contributions outlined in this article.

Abstract

NGOs play a vital role in delivering wetland conservation at all levels. Their role is often under-recognized as many NGOs do not have a formal status and because they deliver such a diverse set of activities. However, from supporting top-level environmental conventions, carrying out research, engaging local communities, and delivering practical conservation work, NGOs are a powerful tool for the delivery of wetland conservation. International and regional NGOs concerned with wetland conservation are described.

delivering practical conservation work, NGOs are a powerful tool for the delivery of wetland conservation.

Wetland NGOs

Delivering work on the ground has long been a central activity of wetland conservation that is delivered by local actors. Many of the challenges that wetlands face are linked to the communities that live in and around them. It is clearly of paramount importance that wetlands are managed well, to provide resources that local people need as well for biodiversity. These range from water itself, food such as fish and birds, building materials, and even cultural and recreational activities. It is in the interest of the local community to manage these resources sustainably and that means they need to be equipped with sufficient knowledge, tools, and resources to achieve this. Whether through managing wetlands sustainably, running engagement and education activities, or carrying out monitoring and practical conservation work, local NGOs are often the best-placed organizations to deliver wetland conservation objectives.

In terms of delivering messages to local people to convince them of the importance of wetlands and their protection, in many instances, local NGOs are more trusted than government, business, or international bodies. They have good local knowledge, are often more likely to be active in the long term, and involve local people in their management or as part of their memberships. They are also seen as more committed to local issues and are not associated with other more political or bureaucratic issues. However, it should be noted that they are often reliant on a few committed individuals, and sometimes have fewer democratic credentials, i.e., they are not voted for by the wider community.

Local NGOs are more often than not part of a wider network of groups, either by sectoral interest or formally as part of a constituted regional, national, or international group. These groupings include regional alliances such as the “mingas” of Ecuador, family groups of indigenous peoples in the same regional area, or groups along geographic features such as rivers or even political boundaries such as local government regions. With increasing communication via internet and social networks, interest groups of NGOs or individuals are also more prevalent, leading to networks that function to promote a specific interest, regardless of geographic proximity.

Regional, National and International NGOs

Regional and national NGOs can exist either as membership groups, with local versions, or as independent groups with a broader interest. So, at this level they can play the role of networks with local representatives, or as international organizations with a campaigning role. Often they fulfil both roles, such as BirdLife or WWF.

Research NGOs play a different role, working with government and private sector groups. Often this will form part of a wider remit, delivering other aspects of wetland conservation. For example, the Tour du Valat (France) has been working for many years on wetland conservation, and is a respected, independent voice for wetland science, from climate change to bird census work. Other NGOs such as WWT (Wildfowl & Wetlands Trust) or Wetlands International also carry out an element of research and hold long-standing datasets for species of wildfowl. Wetlands International is contracted by the Ramsar Convention to carry out the international waterbird census, a highly respected and long-term exercise in estimating the numbers of waterfowl globally.

Network NGOs such as BirdLife, WWF, or IUCN also add huge value to those national and international groups that form part of their membership. In this sense, they create a community of wetland NGOs (note, IUCN includes governmental representatives). This both uses local organizations as a resource to get information, deliver work, or commit finance, as well as providing support and structure to those local groups, through an international voice and trusted expertise. Working through local groups offers a means of validating information used at national level and identifies risks and opportunities. These networks offer a voice at international level too, either directly as stand-alone pressure groups or working in partnership as part of multilateral environmental agreements such as Ramsar. As membership groups they also have resources to carry out wetland research and campaigning and coordination activities for their members.

International NGOs such as WWF and BirdLife play a role to influence and support international policy through multilateral agreements such as Ramsar, the Convention on Biological Diversity, and the Convention on Migratory Species. As officially recognized partners with a defined role, these NGOs are part of the structure of the MEAs, with a history of engagement and commitment to the process. They are generally accepted as "observers" but with the capacity to contribute to debates, provide technical support, and use their national/local contacts to support delivery of the aspirations of the MEA in question.

Less formally established networks such as WWN (related to Ramsar) World Wetland Network, and the Migratory Wildlife Network (related to Convention on Migratory Species) are also actively involved with MEAs, offering an independent and potentially more critical voice. They are not as closely allied to the conventions, and are therefore freer to ensure an independent view of them, particularly when it comes to criticizing the member governments of each convention. Both networks are fairly young, and it remains to be seen how their role will develop. However, it is hoped that they will both provide a strong support mechanism to represent the civil society sector, as well as to influence the MEA decisions on behalf of their members.

Future Challenges

With continuing economic uncertainty in western economies, drastic political changes in North Africa and the Middle East, and massive development and liberalization in the Far East, Russia, and other emerging economies, the role of civil society and NGOs which was already varied is now difficult to summarize or predict. There are both major opportunities for development of their influence and activity, but also growing restrictions in some countries.

From the perspective of MLEAs such as Ramsar and the CBD, the role of NGOs is increasingly important. A focus on indigenous communities and equitable access to natural resources (the Nagoya Protocol of the CBD, see ▶ Chap. 57, "Convention on Biological Diversity (CBD) and Wetland Management") and the impacts of local communities on wetlands are all leading to an increased interest in engaging NGOs and civil society. WWN and the CBD Alliance also offer an increased visibility and opportunity for NGOs to engage in the process of these MLEAs.

Herein lies the challenge to raise the profile, engagement, and influence of NGOs as required by MLEAs while at the same time ensuring that both resources and political support are made available at to them national and local level.

Widely recognized as the world leader in bird conservation, BirdLife applies rigorous scientific approaches, informed by practical feedback from projects on the ground in important sites and habitats, in order to implement successful conservation programs for birds and all nature.

Each BirdLife partner is an independent nongovernmental organization (NGO). Most of the partners have a local or international profile known outside of the partnership. This allows each partner to maintain its individual national identity within the larger global partnership. BirdLife partners work together in a collaborative, coordinated fashion across national boundaries to build a global Partnership of national conservation organizations.

The BirdLife Partnership has six Regional BirdLife Coordination Offices throughout the world and a Global Office in Cambridge, UK. Together these are known as “The BirdLife International Secretariat.” The Secretariat coordinate and facilitate the BirdLife International strategies, programs, and policies.

A Brief History of BirdLife International

The International Council for Bird Preservation (ICBP), the organization which grew into the BirdLife International Partnership, was founded in 1922. On midday of 20 June 1922, a group of interested people convened at the private home of the UK Minister of Finance, the Chancellor of the Exchequer. This erudite group included Dr T. Gilbert Pearson, the cofounder and President of the National Association of Audubon Societies (now National Audubon for USA), Frank E. Lemon, the Honorary Secretary of the Royal Society for the Protection of Birds (RSPB) (UK), Jean Delacour, the President of Ligue pour la Protection des Oiseaux (LPO) (BirdLife in France), and P. G. Van Tienhoven and Dr A. Burdet from the Netherlands. The group was united by their passion for birds and they concluded that the only effective answer to the growing trade of wild bird feathers or the increasing threats to migratory birds had to be through coordinated international action. Following on from this first meeting, a declaration of principles was adopted which stated:

> We believe that in organising a world-wide Committee we can be of much aid to each other in our several countries by the interchange of literature bearing on bird study and bird protection; and by united action we should be able to accomplish more than organisations working individually in combating dangers to bird-life.

Among its earliest campaigns, ICBP called for an end to the international trade in wild bird feathers used in the hat-making trade. Outrage at this trade had been behind the foundation of the National Audubon (BirdLife in the US), RSPB (BirdLife in the UK), and Vogelbescherming Nederland (VBN) (BirdLife in the Netherlands) towards the end of the nineteenth century, and remained a concern for ICBP well into the 1950s, when the fashion died out, at least in part because of awareness-raising by ICBP member organizations. Other early concerns, which remain central for BirdLife today, included the protection of birds on migration, the identification and protection of the areas where birds congregate in large numbers, and the most important sites for threatened birds.

Alarm over the growing extinction crisis led to ICBP, other organizations, and governments to create the International Union for the Conservation of Nature (IUCN) in 1948. Within IUCN, ICBP was given responsibility for compiling data on the world's threatened birds. The first Red Data Book for birds was published in 1966. This Red Data Book, and its successors, had a profound effect on the global conservation agenda by setting conservation priorities and galvanizing government, institutional, and donor support for conservation. ICBP was also instrumental in promoting international wildlife laws, most significantly the Convention on the Conservation of Migratory Species (CMS) and the European directives on wild birds and habitats.

ICBP's structure as a "federation of federations" (national sections including conservation organizations, government agencies, universities, museums, and special interest groups) proved too cumbersome for united conservation campaigns. A new vision was needed and this lead to transition from ICBP to the BirdLife Partnership in March 1993.

Global Overview: BirdLife in Numbers

Today, BirdLife International is the world's largest nature conservation partnership with the 120 BirdLife partners having more than 13 million members and supporters (Fig. 1). This comprises 2.77 million members and 10.8 million people who supported BirdLife Partners in 2012 without being members.

BirdLife partner organizations have worked with 7,475 local groups, including action at 2,750 Important Bird and Biodiversity Areas. This work has involved

Fig. 1 The Partners are shown in *dark grey* and BirdLife Country Programmes in *light grey*

2.7 million children. In addition, BirdLife partners manage or own 1,553 reserves or protected areas covering 4.3 million ha of natural areas globally. Across the world, the BirdLife Partnership directly employs 7,400 staff with a combined budget of US$ 539 million.

Vision, Mission, and Global Strategy

The vision of BirdLife International is stated formally as:

> The BirdLife Partnership wishes to see a world where nature and people live in greater harmony, more equitably and sustainably.

The mission of BirdLife International is:

> The BirdLife Partnership strives to conserve birds, their habitats and global biodiversity, working with people towards sustainability in the use of natural resources.

BirdLife International works towards the vision and mission through the following commitments:

- To prevent extinctions in the wild.
- To maintain and where possible improve the conservation status of all bird species.
- To conserve the sites and habitats important for birds and other biodiversity.
- To sustain the vital ecological systems that underpin human livelihoods and enrich the quality of people's lives.
- In the process, BirdLife will empower people and contribute to the alleviation of poverty and strive to ensure sustainability in the use of natural resources.

BirdLife International's global strategy has been developed from the bottom up by the BirdLife Partnership. The strategy directly supports the commitment of the world's governments to take urgent and effective action to halt the loss of

Table 1 BirdLife's strategic objectives

Save species	Conserve sites and habitats	Encourage ecological sustainability	Enable positive change through people
Prevent extinctions Keep common birds common	Identify, conserve, restore, and monitor the sites and habitats important for birds and other biodiversity Promote resilient ecological networks	Demonstrate and advocate nature's values Promote policies that support sustainability	Catalyze support for nature Promote local conservation action Strengthen the global BirdLife Partnership

biodiversity and to achieve the 20 Aichi biodiversity targets by the year 2020. To achieve this, the strategy has the following four pillars which represent BirdLife's approach to conservation:

1. Save Species
2. Conserve Sites and Habitats
3. Encourage Ecological Sustainability
4. Enable Positive Change through People

Each of the four strategic pillars is underpinned by strategic objectives (Table 1).

Abstract

Conservation International (CI) operates in more than 30 countries empowering societies to sustainably care for nature, our global biodiversity, for the well-being of humanity – building upon a strong foundation of science, partnership, and field demonstration. CI's Greater Mekong Program over the next 5 years aims to: *(a) conserve 1.35 million ha of terrestrial and freshwater systems and 350 km of rivers that produce key ecosystem services (carbon storage, freshwater, food, health, cultural services, and biological diversity) and (b) mainstream the values of the ecosystem services in the national economy making the distribution of the benefits of these services more equitable among people as well as among generations*. About 2.75 million people indirectly and 9,000 people directly are expected to benefit from this work.

Conservation International: Action in the Greater Mekong

Conservation International (CI) operates in more than 30 countries empowering societies to sustainably care for nature, our global biodiversity, for the well-being of humanity – building upon a strong foundation of science, partnership and field demonstration (www.conservation.org). CI's Greater Mekong program over the next 5 year's aims to: *(a) conserve 1.35 million ha of terrestrial and freshwater systems and 350 km of rivers that produce key ecosystem services (carbon storage, freshwater, food, health, and cultural services, and biological diversity); and (b) mainstream the values of the ecosystem services in the national economy making the distribution of the benefits of these services more equitable among people as well as among generations.* 2.75 million people indirectly and 9,000 people are expected to benefit from this work.

The Greater Mekong is the second most biodiverse river system in the world with 1,200 species of fish, 20,000 species of plants, 430 species of mammals, and 800 species of reptiles (CEPF 2012). It is 2,160 km long and flows from China down to Myanmar, Laos PDR, Cambodia and Vietnam, covering an area of about 2.6 million square kilometers and supporting around 326 million people – similar in size to the population of the United States but with a fraction of its wealth (ADB 2012).

The International Union for the Conservation of Nature found that 13% of the freshwater species it assessed were globally threatened, primarily by agriculture and forestry runoff, direct exploitation and/or habitat loss through deforestation, dam construction, and other modifications such as river clearance for navigation (Allen et al. 2012). IUCN also suggested that should all of the hundred plus hydropower dams planned be built on the Mekong, 28% or more of fish species would likely be impacted. And 60% of Mekong people's daily protein comes from fish and fish products (MRC 2005). Fish and other ecosystem services linked to the Mekong such as rice production, transportation, river-based tourism, and sediment deposition were estimated to be worth 33 billion dollars a year; conversely, full hydropower development yields 274 billion dollars in lost services (Costanza et al. 2011).

Where CI: Greater Mekong Works

CI-Greater Mekong works in the 3-S river basin (Sekong, Srepok, and Sesan) which borders Cambodia, Vietnam, and Laos PDR. Although it covers less than 10% of the total Mekong area, the 3-S rivers supply 15% of its sediment and 20% of its water flows (Koehnken 2012; Adamson et al. 2009). CI also works in the Central Cardamoms landscape protecting over 400,000 hectares adopting a "ridge to reef" approach to enhance multiple ecosystem services and protect forested areas. These mountains supply 30% of the Tonle Sap Lake's water supply in the dry season. The Tonle Sap or "Great Lake" work aims to enhance food, water, health, and biodiversity services, and links to development of a more sustainable economy in Cambodia. The lake is also fed by Prey Long forests, where CI works on forest conservation and is developing a Reduced Emissions from forest Deforestation and Degradation

(REDD) project. Within these interconnected focal landscapes and watersheds, CI promotes the protection and valuation of natural capital, sustainable production, markets, and building governance – demonstrating how healthier ecosystems are not only valuable in their own right, but essential for the delivery of healthier economies and for enhancing human well-being.

Landmark Contributions

CI in its 25 years of operation has contributed to the protection of 106 million hectares of land, freshwater, and sea around the world. It was the first to adopt and implement the Hotspots and the High Biodiversity Wilderness Areas methodologies-protecting 53 areas critical for biodiversity. CI then created the Critical Ecosystem Partnership Fund which has funded 137 million dollars of projects and leveraged another $320 million to build capacity for more than 1,600 civil society organizations. CEPF is now funding its second phase of projects in Indo Burma focusing on freshwater and terrestrial ecosystem protection. The 100 million dollar Global Conservation Fund (GCF) invested in 9 million hectares to set aside new and improve the management of existing protected areas – including watersheds and wetlands in Asia, Africa and the Americas.

CI also discovered and documented hundreds of new or endemic species in priority high-biodiversity countries (with 6 of those found in Cambodia); partnered with more than 1,000 local and indigenous organizations to support protection of biodiversity and ecosystems (more than 25 such partners in Cambodia); and impacted policy and corporate decisions that support sustainable development – engaging more than 30 corporate partners. CI-Greater Mekong has granted $4.6 million dollars to partners and trained over 5,000 people in the past 10 years.

Major Activities

Science and Policy

CI science in the Mekong supports policy and more sustainable resource use and decision-making. For example, natural capital metrics are being developed to assess and monitor stocks and flows of ecosystem services; and a Multiple Interface Decision Assessment System will be completed next year to help governments in lower Mekong countries select various hydropower and agriculture development options which have less impact on the Tonle Sap lake. The University of Canterbury in New Zealand and other CI partners are looking at the alternative location, design and operation options as well as payment for ecosystem services options for hydropower. CI-Greater Mekong produced a film “Hydropower Impacts and Alternatives” now being used by NGOS and other partners to promote sustainable 3-S river hydropower development and encourage the use of alternative energy (cambodiahydropower.weebly.com/).

3-S River Basin

The 3-S River Basin provides an important contribution of aquatic biodiversity and ecosystem services linking to the Mekong River, especially with regard to fish habitats (rapids, deep pools, and sand bars) and migration routes. There are currently nine operating dams and 11 projects under construction. Existing dam operations in the Sesan River already cause high and unpredictable fluctuations of water levels downstream and have caused changes in water quality, a major decline of fish populations and other species, and the loss of livelihood and economic security (Piman et al. 2013). The impact of sediment and nutrient flow changes due to both hydropower and land use change on downstream ecosystems such as the Tonle Sap lake Sap lake Sap is also likely to be very significant.

CI-Greater Mekong's work includes supporting and leveraging science depicting the importance of this basin for human livelihoods and ecosystem services – aiming to influence regional hydropower planning discussions. In the future, the program will create trans-boundary protected areas between Cambodia and Laos, and between Cambodian and Vietnam to protect undammed sections of the 3-S rivers. CI-Greater Mekong will also build future scenarios and conduct joint visioning exercises to encourage better cooperation across borders to manage the 3-S rivers for multiple purposes.

Cardamoms/Tonle Sap Scape

The Cardamom Mountain Range covers approximately two million hectares of forested land and is one of the largest remaining areas of natural forest in Southeast Asia. The Central Cardamoms Protected Forest (CCPF) is home to approximately one-third of all Endangered and Rare species listed under the Cambodian Forestry Law, and almost fifty IUCN-listed threatened species (FA 2008). CI-Greater Mekong works with the Forestry Administration and local communities to protect species and their habitats – conducting species research, law enforcement training, and overseeing patrols. Conservation agreements are also implemented to compensate communities for the opportunity costs of conservation (e.g., tilling machines, teacher salaries, etc.).

The CCPF is critical for ecosystem services for thousands of people living within and around its borders, as well as those 30,000 living further downstream in Koh Kong and Pursat provinces (Sousan and Sam 2013). CI-Greater Mekong is also working on sustainable financing options for conservation including a establishing a trust fund, PES projects to fund forest protection in exchange for avoided sedimentation which benefits hydropower developers, and working with economic land concession owners to create sustainable production landscapes.

The Tonle Sap ecosystem depends upon the Mekong, 3-S, and Cardamom Mountains for water, sediment, nutrients, and fish – all of which drive the lake's incredible biodiversity and productivity. According to the Cambodian Fisheries Administration, a single hectare of floodplain in the Tonle Sap lake can produce up to 230 kg of fish a year (FiA 2014). In terms of its value, the overall fishing sector accounts for 10–12% of gross domestic product and contributes more to income, jobs, and food security than in any other country in the world (Baran et al. 2007). The Tonle Sap is very rich in species with over 300 kinds of fish and contains over 1/3 of Cambodia's rarest species (e.g., otters, fish eagles, fishing cats) (CEPF 2012). The lake is vital for national food security, with almost three million people living in or around it directly relying on it to survive and thrive.

CI-Greater Mekong is working with Fisheries Administration and local communities to minimize overfishing and illegal fishing, as well as to protect and replant the flooded forest which is down to 20% of what it once was. Species and flooded forest monitoring take place monthly by trained community members to benefit key species like otters and fishing cats. Dry season pond protection, demarcation, and management of new fish sanctuaries and conservation areas help protect species and ecosystems. These are no take areas which reduce the impacts of fishing pressure and protects critical brood stocks. Research examining the effectiveness of CI's management model is now underway.

CI-Greater Mekong also supports community fisheries – setting them up and training management committees so that they can be in charge of managing their own resources and ultimately receive government financial support to do so. The program also provide business training and helps set up savings groups for women to both increase revenues from fish processing and protect them from income shocks which can place them deeply into debt.

The Greater Mekong program linking science, policy, and field demonstration work is showing how livelihood and biodiversity benefits can result from sound ecosystem management.

C. M. Finlayson et al. (eds.), *The Wetland Book*,
https://doi.org/10.1007/978-90-481-9659-3_143

(Bolen 2000). This was in an era when waterfowl populations in North America were under immense pressure, and hand rearing of game species was considered the main tool for wildlife management. This led to the formation of Ducks Unlimited in Chicago in 1937 by concerned waterfowl hunters under the leadership of Arthur M Bartley and with a mission to conserve waterfowl habitat. Ducks Unlimited Canada (DUC) was formed in 1938 and Ducks Unlimited Mexico (DUMAC) in 1970.

The Mission of Ducks Unlimited is to conserve, restore, and manage wetlands and associated habitats for North America's waterfowl. It promotes responsible waterfowl hunting along with wetland conservation and restoration. These habitats also benefit other wildlife and people. As waterfowl habitat has been degraded and destroyed across much of North America, DU’s vision is to reverse this trend and fill the skies with waterfowl for today, tomorrow, and forever. This is achieved through diverse public and private partnerships to address the range of factors that continue to erode waterfowl habitat across North America. Information on how DU operates and achieves its vision is available at http://www.ducks.org. These activities include working with elected officials and influencing public policy as well as working multilaterally through partnerships with individuals, landowners, agencies, scientific communities, and other entities. It is an example of a grassroots, volunteer-based organization with membership comprising conservationists and outdoor enthusiasts, largely from North America. At the start of 2014, it had 592,388 adult and 48,900 youth members.

The majority of its members are waterfowl hunters. It has an annual income of approximately US$180 million with some 80% or more of this going towards habitat conservation. The income comes from Federal and State habitat reimbursements (37%), conservation easements (13%), sponsors and members (24%), major gifts and donations (21%), and royalties/advertisement (5%). In 2013, it had total net assets of US$ 132 million. It reports to its members through an annual report and national convention and some 4,000 annual events involving members and partners.

Activities

Ducks Unlimited undertakes many activities involving members and partners. These activities are predominantly focused on North American wetlands and waterfowl and also influence and guide similar activities elsewhere in the world. It currently focuses its conservation efforts on the following five regions, all of which are extremely important for waterfowl: Prairie Pothole Region, Western Boreal Forest – Canada, Mississippi Alluvial Valley, Central Valley/Coastal California, and Gulf Coast Prairie. It also has projects in all states and provinces of the USA and Canada and key areas in Mexico and Latin America. It has undertaken more than 20,000 conservation projects in North America. This includes projects across the four flyways – the Atlantic Mississippi, Central, and Pacific flyways. The importance of flyways and the patterns of migration have been investigated for many years through participation in bird banding and more recent technologies for tracking bird movements. These projects have brought together professional scientists from government and nongovernmental organizations, such as DU, and many members of local communities from across the flyways. In addition to collecting valuable scientific information on waterfowl, these programs can support conservation education and awareness initiatives.

Through its many projects and with the support of its members and partners, DU has conserved more than 46,900 km^2 of waterfowl habitat in North America. It has partnerships with a range of corporations, governments, other nongovernmental organizations, landowners, and private citizens to restore and manage areas that have been degraded and to prevent the degradation of existing wetlands. It also works with partners to recommend policies for wetland conservation and promotes the continuation of safe and regulated waterfowl hunting.

Regional conservation initiatives are organized on a geographical basis and serve to link people and resources with critical habitats and recognize the contribution of each region sustaining the future of waterfowl. The following conservation initiatives are underway:

1. **The Alaska Initiative – Born to Fly**: protecting pristine wetland and delta landscapes for breeding and brood-rearing waterfowl.
2. **America's River Initiative**: rebuilding the Mississippi River floodplain by conserving key wintering habitat for waterfowl and reinforcing the region's waterfowling legacy.
3. **Big Rivers Initiative**: restoring the feeding and resting areas along the rivers that make up the Mississippi floodplain and the conserving habitat critical for migratory waterfowl.
4. **Boreal Forest Initiative**: conserving the intact, productive and pristine forests, wetlands, lakes, rivers, and streams.
5. **California Wetlands Initiative**: restoring wintering habitats for waterfowl, other wildlife, and people.
6. **Completing the Cycle Initiative**: ensuring healthy habitat to sustain migratory waterfowl along the Atlantic Flyway waterfowl.
7. **Ducks in the Desert Initiative**: restoring the oases of North America's desert landscape for waterfowl, other wildlife, and people, from the Great Salt Lake to the Lower Colorado River.
8. **Gulf Coast Initiative**: saving critical wintering waterfowl habitat in North America by conserving coastal prairies and marshes along the Gulf Coast.
9. **Great Lakes Initiative**: protecting the waters of the Great Lakes and conserving critical habitat for many species of waterfowl that use this watershed.
10. **Heartland Heritage and Habitat Initiative**: providing innovative water solutions for ducks and people in the Southern Great Plains.
11. **Living Lakes Initiative**: conserving Minnesota and Iowa's wetlands and shallow lakes for waterfowl migrating between the southern wintering and northern breeding grounds each year.

12. **Peaks to Prairies Initiative**: restoring wetlands in the shadow of the Rocky Mountains and conserving the productive breeding populations of ducks.
13. **Preserve Our Prairies Initiative**: conserving North America's highest-priority waterfowl nesting habitat.
14. **Southeast Wetlands Initiative**: supporting the outdoor heritage of the southeastern United States by conserving key habitats for waterfowl.
15. **Southern Prairies & Playas Initiative**: protecting, restoring, and enhancing the grasslands and wetlands of the Southern Great Plains to support migrating waterfowl populations.
16. **Wings and Wetlands Initiative**: assessing impacts of wetland loss and increasing demand for water in Idaho, Oregon, and Washington states.

Progress with such activities and other news are often reported through the web pages of DU, DUC, and DUMAC and also in the DU magazine. The magazines contain many historical and practical articles on waterfowl hunting and are in part supported by revenue from advertisements of waterfowling equipment. Other publications include the Understanding Waterfowl articles that are now standalone and previously presented in the DU Magazine.

While the main focus of DU's work has been in North America, it has assisted with activities elsewhere, encouraging the establishment of similar organizations in New Zealand and Australia, providing technical advice and guidance to the Ramsar Convention on Wetlands, and making its information and knowledge available through individual and institutional networks.

Conservation Methods

DU works closely with wetland and waterfowl biologists and ecologists to assess habitat needs for waterfowl and to monitor how birds respond to environmental pressures. The hallmark of DU's conservation efforts has been habitat restoration and creation. Some of the approaches used to manage wetlands for waterfowl include:

1. **Restoring grasslands** that provide cover and help conceal waterfowl nests and increase the chances of successful hatching.
2. **Replanting forests** that are regularly flooded by overflow from rivers and provide wintering habitat for ducks, and breeding and foraging habitat for other wildlife.
3. **Restoring watersheds** by protecting stream corridors, establishing buffer zones that filter nutrients and sediments, and restoring previously drained wetlands.
4. **Educating landowners** including ranchers to make their land more wildlife-friendly while enhancing the agricultural and recreational values.
5. **Establishing conservation easements** where the landowner agrees to specific development restrictions while maintaining ownership of the land.

The essence of these activities is their reliance on partnerships and science and support of DU's mission and focus on conserving waterfowl both for the present and future.

International Union for Conservation of Nature (IUCN)

83

Claire Warmenbol and Mark Smith

Contents

Abstract

IUCN is a membership Union uniquely composed of both government and civil society organisations. It provides public, private and non-governmental organisations with the knowledge and tools that enable human progress, economic development and nature conservation to take place together.

IUCN is the world's largest and most diverse environmental network, harnessing the knowledge, resources and reach of more than 1,300 Member organisations and some 16,000 experts. It is a leading provider of conservation data, assessments and analysis. Its broad membership enables IUCN to fill the role of incubator and trusted repository of best practices, tools and international standards.

IUCN provides a neutral space in which diverse stakeholders including governments, NGOs, scientists, businesses, local communities, indigenous peoples organisations and others can work together to forge and implement solutions to environmental challenges and achieve sustainable development.

Working with many partners and supporters, IUCN implements a large and diverse portfolio of conservation projects worldwide. Combining the latest science with the traditional knowledge of local communities, these projects work to reverse habitat loss, restore ecosystems such as wetlands, and improve people's well-being.

Introduction

The International Union for Conservation of Nature (IUCN) was founded in 1948 as the world's first global environmental organization (www.iucn.org). IUCN's work focuses on valuing and conserving biodiversity, ensuring effective and equitable governance of nature's use, and deploying nature-based solutions to global challenges in climate, food security, and development.

IUCN's vision is a just world that values and conserves nature. Its mission is to influence, encourage, and assist societies throughout the world to conserve the integrity and diversity of nature and to ensure that any use of natural resources is equitable and ecologically sustainable.

Conserving biodiversity is central to the work of IUCN. IUCN demonstrates how biodiversity is fundamental to addressing some of the world's greatest challenges such as climate change, sustainable development, and food security. To deliver conservation and sustainability at both the global and local level, IUCN builds on its strengths in the following areas:

Science – 11,000 experts setting global standards in their fields, for example, the definitive international standard for species extinction risk – the IUCN Red List of Threatened Species.

Action – hundreds of conservation projects all over the world from the local level to those involving several countries all aimed at the conservation of biodiversity and sustainable management of natural resources.

Influence – through the collective strength of more than 1,200 government and nongovernmental member organizations, IUCN influences international environmental conventions, policies, and laws.

A Brief History of IUCN

IUCN was born out of a gathering of minds organized by Sir Julian Huxley, Director General of UNESCO, which sponsored a congress held at Fontainebleau, France, on 5 October 1948 to establish a new environmental institution. In total 18 governments, 7 international organizations, and 107 national nature conservation organizations agreed to form this institution and signed a "constitutive act" creating an International Union for the Conservation of Nature.

From this beginning, the overriding strategy and policy of IUCN has been to explore and promote mutually beneficial conservation arrangements that suit those promoting development as well as assisting people and nations to better preserve biodiversity.

At all times, IUCN has heavily emphasized as a key operating principle the strong need to cater to and address the needs of nations, peoples, and communities, so that they can take ownership of future, long-term conservation goals and objectives in their local areas.

IUCN's *World Conservation Strategy* of 1980, based on these principles, announced IUCN's ambitions to more effectively promote dialogue among proponents of conservation and economic development. With the emergence of the concept of sustainable development, IUCN is engaged in nations around the world, making available the services of a large pool of specialists, providing local level advice and conservation services, and expanding its networks of committees and regional advisory bodies.

IUCN and the Ramsar Convention

In its headquarters in Gland, Switzerland, IUCN also hosts the Secretariat of the Ramsar Convention on Wetlands. IUCN has hosted the Ramsar Secretariat since 1987 and has been associated with the Convention throughout its development. Prior to this, IUCN and the International Waterfowl and Wetlands Research Bureau (IWRB), now Wetlands International, jointly served as the Secretariat for the Convention. However today, the Convention is an entirely independent body directly responsible to, and at the service of, its contracting parties (Matthews 1993).

IUCN helped to build support for a global treaty on wetlands by supporting the establishment of a program for the conservation and management of wetlands. This program was called the MAR project which stands for the first three letters of wetlands in different languages – MARecages, MARshes, and MARismas. In part through the development and dissemination of promotional products, this project helped boost the image of wetlands and communicate the many benefits derived from them. The ensuing MAR conference stimulated the collection of scientific wetland inventories, first for Europe and the Mediterranean region, then further globally.

IUCN's Commission on Ecology was designated in 1967 to operate the "Wetlands Convention" and draw up recommendations for parties' wetland conservation. A first draft of the Convention text was discussed at the IUCN Headquarters in Morges, Switzerland, that same year. When the Convention treaty was signed in Iran on 3 February 1971, IUCN accepted the role of bureau duties for the Convention Secretariat, in close collaboration with IWRB.

IUCN and Wetlands

In 1985, IUCN together with WWF started a major wetlands campaign called “Life at the Water’s Edge” (Wetlands Conservation Program 1985–1987: Life at the Water’s Edge, WWF/IUCN). This campaign promoted the need for wetland conservation, produced a vast array of communication materials, and set out a clear wetland conservation program.

Over the past four decades, the multiple roles of wetland ecosystems and their value to humanity have been increasingly understood and documented. That millions of people around the world rely on wetlands for livelihoods is familiar now to many. The Inner Niger Delta, for example, hosts about 20% of the population in Mali and generates on average 90,000 tonnes of fish catch per year. The Lower Mekong Delta supports the world’s most productive inland fisheries, valued at around USD three billion, caught each year. These inland fisheries provide 56 million people with up to 80% of their animal protein intake.

IUCN is working with the Ramsar Convention and Contracting Parties and also with grassroots communities and river basin agencies to implement wetland conservation as part of its water management work. The benefits are clear: not only does it help to conserve biodiversity and livelihoods, but wetland conservation brings benefits to water quality, fisheries, and protection against floods.

For example, IUCN has been working since the mid 1980s in the Inner Niger Delta, an incredibly rich wetland covering over 20,000 km^2 harboring high concentrations of biodiversity (Zwarts et al. 2005). Together with IUCN members such as the NGO Walia and Wetlands International, IUCN developed an approach to flooded forest restoration which gave life again to the delta’s fisheries and soil fertility. This successful example of ecosystem restoration stemmed in part from contributions of traditional landowners, local governments, and technical state services.

IUCN also supported the Government of Botswana to develop the Okavango Delta Management Plan, adopted in 2008. The Management Plan demonstrated how wetland management benefits the health of ecosystems, as well as generates jobs, development, and well-being in the process.

In Jordan, the Azraq Basin is one of the most important recharging ground water basins in the region, supplying water to the capital Amman. The basin also hosts the Azraq oasis, a Ramsar site particularly important for migratory birds, with up to a million birds utilizing the area during the course of a single spring migration. The key challenges facing the Azraq basin are water quality deterioration, soil degradation, and social conflict. The IUCN office in Jordan is working closely with managers of the Azraq Ramsar site, communities, and water resource managers in the region to better protect and begin to restore this vulnerable and precious wetland site.

In Asia, IUCN helped the government of Lao PDR to complete the process of accession to the Ramsar Convention in 2010. In acceding to the Convention, Lao PDR committed to conservation and sustainable use of its wetlands at a crucial point in the nation’s rapid and transformative economic development. Upon accession, Lao PDR designated the country's first two wetlands of international significance, the Xe Champhone Wetlands and the Beung Kiat Ngong Wetlands.

IUCN is increasingly promoting the idea of "nature-based solutions" as part of strategies for tackling the big problems the world faces. What does this mean? A nature-based solution can be peat bogs that function as water filtration plants, mangroves that protect shoreline development, braided floodplains that serve as dikes and levees, or wetlands that operate as treatment of industrial effluent. This "natural infrastructure" does not necessarily replace built infrastructure, but it may be a more affordable and durable option. It complements engineered designs as a counterpart, working hand in hand. By investing in natural infrastructure, we invest in the people closest to its pulse. With the right incentives and the right institutions, we can empower people to become part of the solution.

During the sixth World Water Forum in Marseille, IUCN Director General Julia Marton-Lefèvre concluded the opening ceremony with this solutions focus:

> Every human, now and in the future, should have enough clean water for drinking and sanitation, and enough food and energy at reasonable cost. Nature immeasurably strengthens our ability to meet these basic needs – but not if we squander our natural capital through blindness to the unseen wealth at our fingertips. We should ask –from the onset- how nature can be a solution, how natural infrastructure can help us design, build, manage and use existing water systems for the sake of our human development, our tight budgets, and our thirsty populations. Nature never asks for our pity. Yet as we have discovered, nature is always more than ready to work as our equal partner.

C. M. Finlayson et al. (eds.), *The Wetland Book*,
https://doi.org/10.1007/978-90-481-9659-3_103

ICF was founded in 1973 by Dr. George Archibald and Dr. Ron Sauey. ICF's headquarters are located in Baraboo, Wisconsin, USA, with regional offices in China (Harbin), India (New Delhi), Vietnam (Ho Chi Minh City), Cambodia (Phnom Penh), South Africa (Johannesburg), Zambia (Lusaka), and the USA (Corpus Christi, Texas). ICF employs 54 full-time staff members and dozens more project associates, research associates, and interns and sustains a global network of hundreds of specialists working in over 50 countries on five continents. ICF is governed by an international board of 30 directors and has an advisory board drawn from 12 countries.

ICF's headquarters are located on a 240-acre campus in rural Wisconsin. ICF is visited more than 20,000 people each year, and about 30 international colleagues study at ICF annually. The site hosts a captive flock of over 100 cranes, including the only complete collection of all 15 species ever assembled. ICF's campus is a global classroom, featuring live crane exhibits, crane-breeding and crane-rearing facilities, an interactive education center, research library, visitor center, guest house, and nature trails set among 100 acres of restored prairie, savanna, wetland, and forest, and adheres to the highest standards for green building principles.

Crane Conservation

From its beginning, ICF recognized that conserving all 15 species of cranes requires a broad commitment to the people and places essential to cranes. Cranes are among the most endangered families of birds in the world, with 11 of the 15 species threatened with extinction. Many populations are in peril. In sub-Saharan Africa, gray-crowned, black-crowned, wattled, and blue cranes face many threats fueled by rapid population growth and widespread poverty. In Asia, six species are threatened, including Siberian, red-crowned, white-naped, hooded, and black-necked cranes in rapidly developing East Asia, and the sarus crane throughout its range in South and Southeast Asia. The rarest of all cranes, the whooping crane, faces an array of conservation challenges in North America. Consequently, ICF's global priorities span sub-Saharan Africa, East Asia, Indo-Pacific, and North America, while ICF's headquarters in Wisconsin serve as a global center for conservation leadership and training.

ICF's priority programs focus on six conditions essential to securing all 15 species of cranes in the wild:

1. *Mitigating direct threats to crane populations in the wild*. ICF's field programs target the most serious threats to cranes, including illegal trade, shootings, powerline collisions, poisonings, and others. The capture of cranes from the wild for domestication and trade, for example, is one of the most daunting challenges to crane populations, especially in Africa. In collaboration with Wetlands International, ICF studied the black market for cranes in Mali and learned that thousands of cranes were being illegally captured and exported to Europe, the Middle East, and Asia – and 80% or more die through this supply chain. Based on this knowledge, ICF's programs now focus both on reducing the

international demand for cranes by raising awareness among governments, zoo associations, and private collectors and coordinating captive breeding efforts. ICF also supports the most threatened populations with captive propagation and reintroduction efforts, with particular emphasis on establishing a second, self-sustaining population of whooping cranes in the eastern USA.

2. *Securing ecosystems, watersheds, and flyways on which cranes depend, through sustainable resource management*. ICF works to protect and restore vital breeding, staging, and wintering grounds along the flyways traversed by migrating cranes, which include long-term programs for some of the most important wetlands in the world – e.g., the Poyang Lake in China, the demilitarized zone between North and South Korea, the Kafue Flats and Zambezi Delta in southern Africa, the Mekong Delta in Southeast Asia, and the Guadalupe-San Antonio Bay and Estuary in Texas. ICF advances alternative water and land-use practices in these wetlands and the broader watersheds that sustain them, including the environmental flows, invasive species control, fire management, and other land stewardship practices. In southern Africa, ICF is leading international efforts to secure water for key wetlands in the Zambezi River watershed, through controlled releases of water from dams developed for hydropower production.
3. *Bringing people together for conservation action based on their shared values for cranes and the landscapes they depend on*. ICF hosts the Wetlands International – IUCN Species Survival Commission Crane Specialist Group which stimulates and coordinates activities involving over 250 experts from 50 countries. In the 1990s, ICF helped broker agreements between China and Russia to work together to protect and manage crane breeding grounds along the Amur and Ussuri Rivers that divide the two countries. Through the Convention on Migratory Species, ICF brought together 11 diverse nations – including Afghanistan, Azerbaijan, People's Republic of China, India, Islamic Republic of Iran, Kazakhstan, Mongolia, Pakistan, Russian Federation, Turkmenistan, and Uzbekistan – to sign a Memorandum of Understanding for the conservation of Siberian cranes.
4. *Improving local livelihoods and other benefits for communities through the conservation of cranes and their landscapes*. From the rice paddies of north India to the hillsides of Rwanda to the converted agricultural plains of northeast China, cranes live in some of the most densely settled – and impoverished – regions of the world. Conservation solutions in these settings, as well as among more affluent regions, must bring meaningful benefits to local people, and those benefits must be sustained for the long term. At Phu My in Vietnam, for example, locally produced handicrafts from *Lepironia* wetlands are sold in competitive markets of Europe, Japan, and the Middle East. The income generated covers most of the costs for managing this important wetland for sarus cranes and other species. In just 6 years, local income increased fivefold for the community, and crane numbers jumped from 5 to over 250 (30% of the known population).
5. *Empowering conservation leadership for cranes, local communities, and the landscapes they share*. For 40 years and throughout much of the world, ICF has identified and advanced emerging leaders to help cranes and their landscapes. ICF's headquarters, staffed with experts in crane biology, environmental

education, field ecology, captive management, and conservation medicine, are a preeminent center for the training of future leaders. In Southeast Asia, ICF established a network of 18 universities to empower future leaders in wetland ecology and management in the Mekong Region – training more than 250 young lecturers and wetland managers from universities, government agencies, and conservation organizations from eight countries in the region.

6. *Building knowledge for policy and action to secure cranes and crane landscapes*. ICF is a science-based organization whose success is built on its long-term accumulation of knowledge and expertise. At Poyang Lake, ICF research helps national decision-makers understand the importance of natural water-level fluctuations for critically endangered Siberian cranes, many other wetland-dependent species, and for human needs such as transportation, water quality, and fisheries. By linking the ebb and flow of water with the productivity of aquatic plants that cranes feed on ICF research helped quantify the catastrophic impacts that would result from raising and stabilizing waters at Poyang. In India, ICF research uncovered the significant biodiversity value of the densely settled agricultural regions of the northern Ganges plain and identified factors that favor or threaten the functioning of this patchwork of farm fields and small wetlands.

International Peat Society

85

Jack Rieley

Contents

Abstract

The International Peat Society (IPS) is a nongovernmental, nonprofit, multidisciplinary organization of scientific, industrial, and regulatory members. As of 2013, it has 1,450 individual and institutional members from 36 countries. It was constituted in 1968 in Quebec, Canada. The IPS is registered in Finland where the IPS Secretariat is located. The society will celebrate its half century in 2018.

Keywords

Nongovernmental organization · Peatlands · Mires · Conservation · Sustainable use

Introduction

The International Peat Society (IPS) is a non-governmental, non-profit, multidisciplinary organization of scientific, industrial and regulatory members. As of 2013 it has 1,450 individual and institutional members from 36 countries. It was constituted in 1968 in Quebec, Canada. The IPS is registered in Finland where the IPS Secretariat is located. The Society will celebrate its half century in 2018.

e-mail: jack.rieley@nottingham.ac.uk

C. M. Finlayson et al. (eds.), *The Wetland Book*,
https://doi.org/10.1007/978-90-481-9659-3_146

The International Peat Society was formally established at the Third International Peat Congress (Quebec, 1968) building on the success of and interest expressed at two previous peat congresses (Dublin 1954 and Leningrad 1963). Much of the stimulus for its establishment, especially in early post World War 2 years, came from the peat industry that was important for energy generation in several countries including Ireland, Finland, Sweden and the Soviet Union. From the outset, in addition to considerations of the production and industrial utilization of peat, the Society also focused on peat resource survey and classification, peatland agriculture, forestry and horticulture and the chemical, physical and biological properties of peat and peat products.

From the outset, the principal aim of IPS has been to promote international contact and co-operation on all matters concerning the study and wise use of mires and peatlands, peat and peat products and related materials in order to advance knowledge and understanding in the cultural, socio-economic, scientific and technical fields. To achieve its goals the IPS, through its nine Commissions and 17 National Committees, organizes conferences, symposia and workshops and publishes research results from science and industry. IPS serves as a forum to get and to keep peat and peatlands experts, from different fields of business, science, culture and regulatory bodies, in touch with each other.

IPS is managed by an **Executive Board**, consisting of the President of the Society, two Vice Presidents and 2-6 ordinary members who are elected for terms of four years on nominations by the IPS National Committees. To reflect the balance of industry and science, Executive Board members come from both areas with emphasis placed on cultural and geographical balance. With the exception of the Presidents, only one Board member from each country can be elected to the Board. Decisions of the Executive Board are implemented by the **Secretariat** that currently consists of the Secretary General (part time) and Communications Manager (full time) who also carry out the routine management of the Society.

The highest decision-making organ of the International Peat Society is the **Annual Assembly**. It comprises one representative from each National Committee. In addition, other members of the IPS can attend as non-voting observers. The Annual Assembly approves the accounts, the annual report, plan of activities and the budget of IPS. It also elects the President, two Vice-Presidents and members of the Executive Board.

At the national level IPS operates through its **17 National Committees** or the Secretariat in countries without one. In countries with a National Committee, all interested organizations, corporations, foundations and individuals are affiliated to the Society through the National Committee concerned.

The main activities of the International Peat Society are conducted through its nine **Commissions** that act as subject groups within specific fields.

- Commission I - Stratigraphy, inventory and conservation of peatlands
- Commission II - Utilization of peat and peatlands for horticulture, energy and other economic purposes
- Commission III - Agricultural use of peatlands and peat
- Commission IV - Chemical, physical and biological characteristics of peat
- Commission V - Restoration, rehabilitation and after-use of peatlands
- Commission VI - Peat balneology, medicine and therapeutics
- Commission VII - Ecology and management of forested peatlands
- Commission VIII - Cultural aspects of peat and peatlands
- Commission IX - Tropical peatlands

Membership of IPS Commissions is open to all members who are interested in the subject. When required, working groups are established to plan and conduct specific projects. For example, in 2005, a joint cross-Commission Working Group on Peatlands and Climate Change was established comprising representatives of all nine Commissions and a number of external experts. This resulted in the publication of a benchmark book in 2008 – “Peatlands and Climate Change” edited by Dr Maria Strack.

The Chairs of the Commissions together with the 2nd Vice President form the Scientific Advisory Board (SAB)of IPS, which elects its own Chair and Secretary annually. SAB normally meets twice a year in association with other IPS meetings or by Internet. The SAB provides the Society with advice and information on matters of scientific, technical and cultural importance, drawing upon the pool of knowledge available in the Commissions and elsewhere and promoting and disseminating research results.

The **International Peat Society** regularly holds Symposia, Workshops and other meetings in different parts of the world. An **International Peat Congress** is organized every 4th year. Moreover, the IPS encourages its members to attend conferences and meetings of other organizations dealing with peat and peatland research.

IPS Member Services

IPS membership confers various privileges, publications and services. The IPS website offers a range of services available to members only who receive a personal user name and password in order to gain access (www.peatsociety.org). Members are able to view and download the proceedings of International Peat Congresses, peat and peatland symposia, workshops and similar events as PDF files for their own use. In addition, it is possible to see and contact other IPS members via the member database, if they have made their data available.

International Peat Congresses

In accordance with its constitution, IPS has held twelve international peat congresses since its inauguration or one every four years, making fourteen in all when Dublin (1954) and Leningrad (1963) congresses are included. The Fourteenth Congress that was held in Stockholm, Sweden in June 2012 was attended by 602 participants from 33 countries. The Fifteenth Congress will be held in August 2016 in Kuching, Sarawak, the first time in a tropical country.

Publications

One of the major tasks of the IPS is publication of information of interest to members and the general scientific community. Besides publishing scientific papers in the International on-line journal **Mires and Peat** and **proceedings** of congresses, conferences and symposia, the International Peat Society also publishes books, policy advisory information and statements, a monthly e-mail newsletter **Peat News** and, twice annually, the magazine Peatlands International. *Peatlands International* consists of about 50-60 pages of background reports on peat and peatlands, reviews of conferences and books, research findings, business reports and internal IPS information.

UK Carbon Story
70 Years Peat Industry in Finland
Peat as Natural Cap
The magazine for members and friends of the International Peat Society

International Collaboration and Links

Over the years, formal and informal collaboration and links have been established with a number of other organisations with an interest in peatlands and peat including UNESCO, FAO, IUFRO, ISHS, ISSS, IMCG, SWS. IPS has observer status on the Scientific Technical Review Panel of the Ramsar Convention. Individual members of IPS are involved in many national and international agencies and conventions that have interest in peatlands and peat, including CBD and UNFCCC.

Mires and Peat - The joint Scientific Journal of IPS and IMCG

Mires and Peat is an on-line, open access scientific journal published jointly by the International Peat Society and the International Mire Conservation Group (IMCG). It was launched in 2006. Mires and Peat publishes high-quality research papers on all aspects of peatland Science, technology and wise use, including:

- ecology, hydrology, survey, inventory, classification, functions and values of mires and peatlands;
- scientific, economic and human aspects of the management of peatlands for agriculture, forestry, nature conservation, environmental protection, peat extraction, industrial development and other purposes;
- biological, physical and chemical characteristics of peat; and
- climate change and peatlands.

Short communications and review articles on these and related topics are also considered; and suggestions for special issues of the Journal based on the proceedings of conferences, seminars, symposia and workshops are welcomed. The submission of material by authors and from countries whose work would otherwise be inaccessible to the international community is particularly encouraged.

International Water Management Institute 86

James Clarke and Mathew McCartney

Contents

Abstract

The International Water Management Institute (IWMI) is a non-profit, scientific research organization focusing on the sustainable use of water and land resources in developing countries. IWMI works in partnership with governments, civil society and the private sector to develop scalable agricultural water management solutions that have a real impact on poverty reduction, food security and ecosystem health. IWMI is a member of CGIAR, a global research partnership for a food-secure future.

https://doi.org/10.1007/978-90-481-9659-3_142

Introduction

The International Water Management Institute (IWMI) is headquartered in Colombo, Sri Lanka, with regional offices across Asia and Africa. It is one of 15 CGIAR centers which working together and with partners seek to advance agricultural science and innovation to enable poor people, especially women, to better nourish their families, and improve productivity and resilience so they can share in economic growth and manage natural resources in the face of climate change and other challenges seek a mission.

IWMI leads the CGIAR Research Program on Water, Land and Ecosystems (WLE) which combines the resources of 11 CGIAR centers, the Food and Agriculture Organization of the United Nations (FAO) and numerous national, regional and international partners to provide an integrated approach to natural resource management research. WLE promotes a new approach to sustainable intensification in which healthy functioning ecosystems are seen as a prerequisite to agricultural development, resilience of food systems and human well-being.

Mission and Vision

The institute's mission is *to provide evidence-based solutions to sustainably manage water and land resources for food security, people's livelihoods and the environment*. IWMI's vision is for *a water-secure world*.

IWMI works through collaborative research with many partners in the North and South, and targets policymakers, development agencies, individual farmers and private sector organizations.

From the immense damage caused by water-related disasters to the growing problems of water scarcity, IWMI research is seeking solutions to complex problems. Its focus is on the world's poorest and most vulnerable people.

A Brief History of IWMI

IWMI was founded as IIMI, the International Irrigation Management Institute, in 1985. Its original focus was on poorly performing irrigation systems across Asia. IIMI made a major contribution to the improvement of irrigation management by working with stakeholders at all levels on the design, operation and maintenance of irrigation systems. The wealth of knowledge and capacity developed during those early years remains in place today and has fuelled further expansion beyond the Institute's original mandate.

IWMI's early research revealed that water management problems are rarely solely technical, but are often caused by institutional inadequacies. This led to the institution's current emphasis on an interdisciplinary approach to water management. This paradigm has resulted in considerable advances in areas such as water rights, pricing and financing of water resources. IWMI has looked at ways to create positive incentives for farmers and policy makers to manage water more equitably and efficiently. IWMI also carried out some of the early and most significant work on gender and irrigation.

IWMI's unique mix of technical specialists and social scientists has enabled it to tackle complex problems of water management that have confounded the best efforts of policy makers and water users. Pioneering work on groundwater governance, formal and informal water institutions, and broader issues of water and society has made IWMI a market leader in resource management research for policy solutions.

IWMI was awarded the Stockholm Water Prize in 2012.

Research Themes

IWMI's research examines the "water-food-environment nexus", adopting a multi-disciplinary approach and balancing efficiency and productivity objectives with equity and sustainability concerns.

Seven key Research Themes help IWMI to more effectively produce impact for the benefit of poor farmers, whose livelihoods depend on agriculture and for whom access to water for productive purposes is a key constraint. IWMI recognizes the scope for a more proactive role in knowledge application to increase impact-particularly by interacting closely with other research institutes, policymakers, donors, partners and user communities.

1. **Ecosystem Services** recognizes the centrality of ecosystem services for the sustainable intensification of agriculture, and investigates how landscapes, including rivers and wetlands, can be better managed to deliver ecosystem services that are critical for livelihoods and people's well-being
2. **Governance, Gender and Poverty** focuses on promoting gender and social equity, and the sharing of benefits across borders. The theme generates research evidence to foster new and more effective policies, governance and institutional arrangements, and innovative management solutions that seek to optimize the benefits to key stakeholders, including disadvantaged women, men and youth;
3. **Resource Recovery, Water Quality and Health** seeks opportunities to mitigate the negative impacts of human activities on water quality, the environment and health. The theme's current research focuses on safe wastewater use, and business models for resource recovery from wastewater, fecal sludge, and domestic and agro-industrial waste.
4. **Revitalized Irrigation Systems** addresses the complex issues of improving irrigation system productivity and sustainability, looking at policy, institutions and management and technical aspects and solutions. Work includes the benchmarking of irrigated systems and other innovative management tools, as

well as exploring opportunities for scaling up appropriate modernization technologies.
5. **Sustainable Agricultural Water Management** works on sustainable intensification of rainfed agricultural and aquatic systems. The theme investigates technical, policy and institutional interventions to improve access to and management of productive water and land resources for poor and vulnerable agricultural communities.
6. **Water Availability, Risk and Resilience** incorporates hydrological and hydrogeological assessments at multiple scales under current and future climate scenarios, provides services to other themes for modelling of water resources scenarios, and enhances availability and delivery of water resources data through the use of earth observing system satellites and information and communications technology.
7. **Water Futures** conducts research to improve the understanding of the interplay between the decision-making environment and the behaviour of the physical hydrological systems.

Wetland Research at IWMI

IWMI recognizes the importance of wetlands and the vital role that they play in supporting and enhancing the livelihoods of people in developing countries. In many of the countries that IWMI works, wetland agriculture brings opportunities as well as threats. Farmers can enhance the natural productivity of wetlands and a significant proportion of the value of many wetlands is derived from agriculture. However, if insufficient attention is paid to other wetland services, in particular regulating and socio-cultural benefits, wetland degradation results, with a concurrent decrease in agricultural potential. The dilemma remains how to maximize the benefits of agriculture whilst simultaneously minimizing the adverse impacts on other valuable ecosystem services.

IWMIs works on two key objectives for wetland research:

- To protect ecosystem services, livelihood and water productivity in wetlands through better knowledge of how agricultural activities impact wetland functions.
- To reduce poverty through improved agriculture, fisheries, and livestock management in wetlands via identification of effective management strategies and policies to protect vital ecosystem services.

IWMI was elected an International Organization Partner (IOP) of Ramsar at the Convention of the Parties in 2005. IWMI scientists contribute to the Working Groups of the Conventions Scientific and Technical Review Panel (STRP). Over the past few years, IWMI has increased understanding of both the value of wetland agriculture for poverty alleviation and livelihoods as well as the impact of agriculture on wetlands. IWMI has also made significant investments to raise awareness and ensure dissemination and uptake of this knowledge.

Building Capacity

IWMI has a long standing commitment to develop the talents of scientists in the developing world. Hundreds of local researchers have worked for the institution, many gaining PhD's or other qualifications. Many of these individuals are now senior figures in water management and research in Africa and Asia.

Outreach and Uptake

IWMI has consistently sought to turn its science into action. It is strongly committed to the notion that its publicly funded research should be regarded as international public goods, freely available to as many people as possible. IWMI publishes policy briefs and syntheses of current thinking which are available online and though leading digital repositories worldwide. IWMI further disseminates its work online making extensive use of social media, mainstream news outlets, multimedia and other digital formats. IWMI's Water Data Portal allows the public to access its databases online. Its remote sensing and geographical information systems facility, GRandD, gives researchers across the world improved access to spatial data.

Recent Publications

The following are examples of IWMI's research reports in the field of wetland management:

Society of Wetland Scientists

87

Robert J. McInnes

Contents

Abstract

The Society of Wetland Scientists (SWS) is an international organization of approximately 3,500 members dedicated to fostering sound wetland science, education, and management. The Society was formed in March 1980. Arranged globally in chapters and working through specialist interest groups, the mission of the Society of Wetland Scientists is to promote understanding, scientifically based management, and sustainable use of wetlands.

Keywords

Non-governmental organization · International cooperation · Wetland conservation

R. J. McInnes (✉)
RM Wetlands and Environment Ltd, Littleworth, Oxfordshire, UK
e-mail: rob@rmwe.co.uk

C. M. Finlayson et al. (eds.), *The Wetland Book*,
https://doi.org/10.1007/978-90-481-9659-3_140

Background

The Society of Wetland Scientists (SWS) is an international organization of approximately 3,500 members dedicated to fostering sound wetland science, education, and management. The Society was formed in March 1980. It was the inspiration of Richard Macomber, a biologist with the US Army Corps of Engineers Board of Rivers and Harbors. Back in the 1970s wetland ecologists at the Corps of Engineers did not have access to a suitable forum for discussing wetland science issues free from political concerns. The Society gave them the opportunity to open up dialogues with their colleagues and beyond.

Today, SWS is a dynamic society with members on every continent (with the exception of Antarctica). The Society represents a rich cross-section of disciplines and backgrounds including members from academia, government officers, private consultancies, nongovernmental organizations, and intergovernmental organizations. The Society is assembled into regional chapters both within the USA and beyond. The Society currently recognizes the following chapters:

- USA – Alaska
- USA – Central
- USA – Mid-Atlantic
- USA – New England
- USA – North Central
- USA – Pacific Northwest
- USA – Rocky Mountains
- USA – South Atlantic
- USA – South Central
- USA – Western

The Society also recognizes the following non-USA chapters:

- Asia
- Oceania
- Canada
- Europe
- South America
- International (all other countries)

In addition to the regional chapters, the society also supports special interest sections which allow members to network and promote activities that address subject areas ranging from science to policy. As of spring 2014, the Society has the following seven special interest sections: Biogeochemistry, Global Change Ecology, Peatlands, Ramsar, Restoration, Wildlife, and Women in Wetlands.

Mission and Goals

The mission of the Society of Wetland Scientists is to promote understanding, conservation, protection, restoration, science-based management, and sustainability of wetlands.

To achieve this mission, the Society of Wetland Scientists will:

- Be recognized as the world leader in wetland science
- Lead the education of wetland professionals and the public regarding wetland science and its applications
- Promote the development of wetland science programs around the world, particularly in developing countries
- Foster diversity among SWS members and other wetland professionals
- Promote sound science in wetland policy and stewardship

The Society of Wetland Scientists advocate that wetland science will:

- Form the basis of the public's understanding of the important ecosystem services of wetlands
- Constitute a rigorous interdisciplinary endeavor and body of knowledge
- Provide the foundation for management, restoration, conservation, protection, and policy

Publications

SWS produces an international journal concerned with all aspects of wetlands biology, ecology, hydrology, soils, biogeochemistry, management, laws, and regulations called *Wetlands*. The journal is recognized as the premier outlet for communicating research to an expanding community of international and interdisciplinary wetland professionals. The journal includes full length articles, short notes, and timely review articles.

In addition to the journal, SWS also publishes a quarterly publication called *Wetland Science & Practice* which showcases examples of wetland issues and acts as a communication tool across the Society's membership.

Meetings

SWS holds an annual meeting which brings together wetland professionals from around the world. In addition to the main annual SWS meeting, individual chapters hold their own meetings at a local level.

For more information on the Society of Wetlands Scientists see www.sws.org.

South Africa's National Wetland Rehabilitation Programme: Working for Wetlands

88

John A. Dini and Umesh Bahadur

Contents

Abstract

Like many other countries, South Africa has experienced high levels of wetland loss and degradation as a result of human activities. A vehicle through which to undertake much needed extensive wetland rehabilitation was provided through government's Expanded Public Works Programme, which seeks to provide work and training to significant numbers of unemployed people. The resulting programme, Working for Wetlands, now invests substantial public funding in the rehabilitation and wise use of wetlands in a manner that maximizes employment creation, supports small emerging businesses, and transfers skills to its beneficiaries. A series of case studies produced through a four year research

programme illustrates some of the benefits of this work, including improved livelihoods, protection of agricultural resources, enhanced biodiversity, cleaner water and reduced impacts from flooding.

Keywords
Wetland rehabilitation · South Africa · Working for Wetlands Programme · Poverty reduction · Livelihoods

Background

South Africa's wetlands collectively play an important role in sustaining the country's ecology and economy. Yet despite these vital linkages between wetlands and people, wetlands have been severely affected by the same human activities that have dramatically altered South Africa's landscapes over the past few centuries. Although no systematic national survey of wetland loss has been undertaken, studies in several major catchments have revealed that between 35% and 60% of the wetlands, and the benefits they provide, have been lost or severely degraded (Kotze et al. 1995). It is likely that the extent of wetland loss for the country as a whole lies within this range, and consequently it was not surprising that the 2011 National Biodiversity Assessment identified wetlands as the most threatened ecosystem type in South Africa (Driver et al. 2012).

A pivotal response by the government to this state of affairs was the establishment in 2000 of a national wetland rehabilitation programme, known as Working for Wetlands. The decision to create such a program came about through the convergence of several driving forces. It drew on objectives in environmental, biodiversity, water, and agriculture policies, and capitalized on the growing recognition that wetland degradation is not necessarily permanent, and that it is possible to reinstate at least some ecosystem services through rehabilitation. A foundation was provided for the creation of the program, in the form of another pioneering government initiative. Since 1996, the Working for Water programme has been engaged in removing thirsty invasive alien plants that pose a threat to the country's water security, agricultural productivity, and biodiversity. The nongovernmental Mondi Wetlands Project recognized that the labor-intensive model pioneered by Working for Water would be equally suited to the activities involved in rehabilitating wetlands and lobbied government to begin experimenting in this direction.

Perhaps the most significant factor enabling the emergence of Working for Wetlands was the availability of government funds earmarked for employment creation and poverty reduction, through the Expanded Public Works Programme (EPWP). This government-wide initiative was set up to draw significant numbers of unemployed people into the productive sector of the economy, gaining skills while they work and increasing their capacity to earn income. The ability to turn wetland rehabilitation into a labor-intensive process unlocked a magnitude of financial resources and political support that was previously inconceivable to cash-strapped government departments responsible for biodiversity conservation and natural resource management.

Thus, Working for Wetlands pursues its mandate of wetland rehabilitation and wise use in a manner that maximizes employment creation, supports small emerging businesses, and transfers skills to its beneficiaries. In line with EPWP norms, the program targets those groups most excluded from the mainstream economy, with particular emphasis on women, youth, and people with disabilities.

All rehabilitation interventions aim to improve the condition and functioning of the ecosystem and address both causes and effects of degradation. Typical project activities include:

- Building concrete, earthen, or gabion structures to arrest erosion and trap sediment, and resaturate drained wetland areas
- Plugging artificial drainage channels
- Addressing other causes of degradation, such as poor agricultural practices and invasive alien plants
- Plant propagation, revegetation, and bioengineering
- Building boardwalks, bird hides, and interpretive signboards to enhance the recreational, tourism, and educational value of rehabilitated wetlands
- Concluding contractual agreements with landowners to secure the rehabilitation work, prevent further degradation of wetlands, and influence land use practices
- Providing community members with part-time employment and training to monitor completed rehabilitation once the work is completed

Since its formation in 2000, Working for Wetlands has on average rehabilitated 79 wetlands per year, thereby improving or securing the condition of approximately 6,150 ha of wetland area per year. In the process, the program has provided employment for an average of 1,650 people each year. In line with the emphasis of the EPWP on training, Working for Wetlands has provided a yearly average of 17,300 days of training in both vocational and life skills.

This large-scale investment of public funds in wetland rehabilitation stimulated a range of supporting activities, including the publication by the Water Research Commission in 2008 of an eleven volume series of reports, manuals, and guidelines for wetland assessment and rehabilitation (Dada et al. 2007). This helped to strengthen the scientific and technical foundation for the program's work which, together with an investment in wetland inventory and classification, enhanced the scope to plan and undertake systematic rehabilitation at catchment scale.

Benefits accruing from the wetlands rehabilitated by Working for Wetlands include improved livelihoods, protection of agricultural resources, enhanced biodiversity, cleaner water, reduced impacts from flooding, and sustained baseflows in rivers (Kotze and Ellery 2008). A series of case studies that illustrate some of these outcomes are presented below.

Case Study 1: Healthy Wetlands, Healthy People: Livelihoods and Rehabilitation of Manalana Wetland

The Manalana wetland, near Bushbuckridge in Mpumalanga Province, was severely degraded by erosion that threatened to consume the entire system if left unchecked. Altogether about 70% of the local population make use of the wetland in some way. These wetland users are typically women between 35 and 70 years of age from single-headed households. The wetland was thus considered to offer an important safety-net, particularly for the poor, contributing about 40% of the food grown locally. As a result, Working for Wetlands partnered with a locally based NGO in 2006 to stabilize erosion and improve the wetland's ability to continue providing its beneficial services, while the NGO worked with wetland users to implement more sustainable cultivation practices.

An economic valuation study completed in 2008 (Pollard et al. 2008) revealed that:

1. The annual value of livelihood benefits derived from the degraded wetland was a mere 34% of what could be achieved with an investment in rehabilitation.
2. After rehabilitation, the wetland now contributes provisioning services conservatively estimated at 3,466 Rand (about USD 392) per household per year to some 70% of local households, in an area where 50% of households survive on an income of less than 5,700 Rand (USD 644) per year.
3. The net present value of the livelihood benefits (1,995,885 Rand or USD 225,500) provided by the rehabilitated wetland over a 50-year period is more than double the cost of the rehabilitation interventions (947,328 Rand or USD 107,030), including monitoring and maintenance over the same period, indicating a very favorable return on Working for Wetlands' investment.
4. Manalana wetland acted as a safety net that buffered households from slipping further into poverty during times of shock or stress.

Case Study 2: Restoring the Kidneys of the Landscape

The diverse Rietvlei wetland system is situated immediately upstream of the Rietvlei Dam within a 4,000 ha nature reserve just outside the capital city of Pretoria. The dam has provided Pretoria with drinking water since 1934, producing about 41 million liters per day, or 3% of the city's current requirement. Until recently, the Rietvlei wetlands were heavily eroded and desiccated, having been drained for cultivation and peat mining before the area was proclaimed a nature reserve.

In recent years, the dam has become severely overloaded with nutrients and other pollutants, as its highly urbanized catchment has received increasing volumes of treated domestic sewage and industrial effluent. As a result, the dam is plagued by blooms of blue-green algae, which cause bad tastes and odors in the water that are difficult to remove and require expensive treatment, as well as posing potential threats to health.

Partly in response to this situation, in 2000, Working for Wetlands formed a partnership with the municipality to rehabilitate wetlands upstream of the dam, with the primary objective of improving their ability to purify the water flowing into the dam. Interventions included gabion; concrete; and earthen structures to control erosion, rewet the organic soils, increase retention time of water, and ensure even distribution of flow across the wetland.

Monitoring results show that the rehabilitated wetlands are improving the quality of water flowing into the dam (Masupa and Makhado 2006) with ammonia levels down by 53%, nitrates by 77%, fluoride by 24%, and sulfates by 4%, compared to upstream of the wetlands. This reduction in pollutants entering the dam is contributing to reduced algal growth, thereby reducing the costs of treating the water for human consumption.

Case Study 3: Wetlands and Flood Mitigation in the Krom River

The Krom River in the Eastern Cape Province previously contained some of the largest wetlands of their type in South Africa. However, it is estimated that half of these have been lost as a result of infestation by alien vegetation and destructive human activities such as large-scale cultivation on floodplains. The catchment, which supplies the city of Port Elizabeth with about 40% of its water, has been the focus of concerted action by Working for Wetlands and Working for Water to rehabilitate wetlands and eradicate invasive alien plants. Since 2001, ten large structures have been built to combat erosion that threatened the remaining large intact wetlands.

In 2006, the Krom River experienced its most severe floods since measurements began in 1938, resulting in heavy loss of life and property. The remaining wetlands played a key role in managing the floods, slowing the velocity and destructive potential of the floodwaters, and trapping sediment. The wetlands proved crucial for reducing further potential damage downstream. The Working for Wetlands structures accomplished their purpose and the two main wetland basins emerged from the floods largely unscathed.

There was no happy ending for the rest of the valley. Where wetlands had been destroyed to make way for cultivated fields, parts of the floodplain and river banks were carried away by the floodwaters. Large volumes of sand were dumped onto the remaining fields, and the rest of the sediment was deposited in the Churchill Dam further downstream. In some places, the river was gouged down to bedrock level. Infrastructure and houses were swept away, and many fields on the floodplain were completely destroyed.

Case Study 4: The Story of Pilot Malele

Mr Pilot Malele was unemployed prior to joining Working for Wetlands in 2002. He had completed his secondary schooling, but financial constraints prevented him from continuing his education further. Prior to joining the program, Pilot relied on irregular, short-term, informal jobs to survive, but these did not contribute to improving his quality of life.

Working on the Sand River project, Pilot seized the training opportunities made available through the program and was appointed as a contractor, managing a team of 12 people drawn from his community. The team's main task involved stabilizing gully erosion through the construction of gabions, sloping, and revegetation of the wetland.

Participating in an evaluation of the socioeconomic impact of Working for Wetlands, Pilot indicated that his life had improved tremendously since he joined the program (Schuyt 2005). The formalized and secure employment enabled him to start a family, build a house for his wife and children, and build additional rooms to accommodate his parents and siblings. A particular source of satisfaction was being able to provide his children with the education that his parents could not afford to provide for him. A major highlight of his life was being able to buy a car, something he never dreamt of growing up in a poor family.

Together with another Working for Wetlands contractor, Pilot used the skills he gained through the program to start a company in order to compete for government tenders. Pilot's story, and that of many others employed through Working for Wetlands and similar programs, shows how such opportunities, coupled with honest effort and determination, can change lives and surmount the most disadvantaged of circumstances.

Future Challenges

Despite these successes, significant challenges remain. The program is evaluating whether its protocols for site selection, and the types of rehabilitation interventions chosen, produce the optimal return on investment. This reflection derives from the realization that the program's footprint, in terms of number of wetlands rehabilitated per year, is dwarfed by the number of wetlands requiring rehabilitation by two orders of magnitude. Working for Wetlands is also being challenged to expand its activities to include securing wetlands that are in good condition, rather than the current focus on rehabilitation of degraded wetlands. The major source of the program's funding, the EPWP, continues to dictate the types of activities that can be undertaken. With strong political pressure to maximize job creation, there is an ever-present risk of the means (labor-intensity) becoming the end. Nonetheless, the program is diversifying its funding sources, with increasing interest being shown by private landowners, especially forestry companies. A fledgling mitigation banking system, being piloted by regulatory authorities, also shows promise as a provider of funding and driver of demand for rehabilitated wetlands. Lastly, as the cumulative number of wetlands rehabilitated increases every year, the challenge of monitoring and maintenance of rehabilitated wetlands, and ongoing engagement with landowners and wetland users, grows correspondingly.

Abstract

The Nature Conservancy (TNC) is a membership-based nongovernmental organization with headquarters in the USA. It has more than one million members and addresses conservation issues across many landscapes and ecosystems, including rivers and wetlands, as well as coastal and marine systems. It works globally to ensure the conservation and restoration of ecologically important lands and waters and to support the ongoing provision of ecosystem services that provide many benefits for people. It comprises a network of offices and field stations across all states of the USA and in more than 35 countries.

https://doi.org/10.1007/978-90-481-9659-3_109

Introduction

The Nature Conservancy (TNC) is a well-established membership-based nongovernmental organization with headquarters in Arlington, Virginia, in the USA. It has more than one million members and addresses conservation issues across many landscapes and ecosystems, including rivers and wetlands, as well as coastal and marine systems. It works globally to ensure the conservation and restoration of ecologically important lands and waters and to support the ongoing provision of ecosystem services that provide many benefits for people. It comprises a network of offices and field stations across all states of the USA and in more than 35 countries.

Its conservation work is based on the best available science, including that undertaken by its own staff as well as by many partner organizations, including governments, research institutions, and nongovernmental and community-based organizations. Information about the organization and its current activities are presented in the Annual Reports (see The Nature Conservancy 2014a) and through an extensive webpage (www.nature.org).

It is governed as a single, tax-exempt organization by a worldwide, volunteer board of directors and is managed from its worldwide office in Arlington. It is organized as a single organization rather than as separate local legal entities with ultimate responsibility for all operations being with the board. Responsibility for day-to-day operations is delegated to the president and chief executive officer with each state and country program being run by a director. Programs in the USA and several in other countries are advised by volunteer boards of trustees.

History

TNC was formerly known as the Ecologists Union that was formed in 1946 with the purpose of taking direct action to save threatened areas. The name was changed to The Nature Conservancy in 1950, and it was incorporated as a nonprofit organization in the District of Columbia in the USA in 1951. Partnerships, including those with governments and the private sector, are at the core of TNC's approach for ensuring it has the means to support public policies that protect and sustain the many and varied ecosystems and biota globally. Its main conservation mechanism for many years has been the Land Preservation Fund that has successfully enabled the organization to provide repayable loans for conservation activities.

The history and milestones of TNC's extensive conservation activities are documented on its webpages and in its annual reports. A number of examples of activities addressing wetlands and wetland management issues are listed below. These are extracted from 2014 Annual Report (The Nature Conservancy 2014a) with further information being available on the webpages in other publications (see www.nature.org/science-in-action/our-scientists/keep-up-with-our-scientists.xml?intc=nature.tnav.science.list).

1. **Caribbean Expansion** – On its southern peninsula and northern coast, Haiti has established its first marine protected areas (MPAs), encompassing a total of 402,881 acres, using conservancy assessments and mapping. TNC scientists are now assisting the Caribbean nation in managing its new MPAs, employing drones to help map and monitor the most important coastal sites. The conservancy is also training the staff of Cuba's National Center for Protected Areas.
2. **Gulf Coast Land and Water –** Powderhorn Ranch, a mosaic of dense live oak forests, coastal prairies, salt marshes, and wetlands, was secured by a partnership between the conservancy, The Conservation Fund, and the Texas Parks and Wildlife Foundation. The ranch's tidal bayfront protect vitally important seagrass beds and mollusc reefs. The National Fish and Wildlife Foundation funded a significant portion of this project using fines from the Deepwater Horizon oil spill. Powderhorn is slated to become a state park with ownership turned over to the Texas Parks and Wildlife Department.
3. **Technology Aids Birds** – Using satellite images and data crowdsourced from eBird.org, TNC scientists mapped when and where migratory birds, including sandhill cranes, need habitat in California's Central Valley. A TNC team, including an economist, then implemented a first-of-its-kind auction to rent and flood farm fields at the exact time and location needed by the birds. The pilot was a success, with more than 40 participating farms creating additional areas of wetland habitat at a critical time for migratory birds.
4. **The Colorado Flows –** Using an innovative water-banking model and a trust to acquire water rights, TNC joined with partners to ensure that the Colorado River delta received dedicated water flows for the first time in nearly half a century. Due to over-allocation of the Colorado River for cities, agriculture, and other uses in the USA and Mexico, the river no longer reaches the Gulf of California – harming fish and shrimp habitat – and has stopped regularly flowing through its delta, a critical habitat for resident and migratory bird species.
5. **Re-creating Floodplains –** TNC has joined with public and private partners to launch Floodplains by Design, an innovative effort along the major rivers that flow into Washington state's Puget Sound. Over the coming 20 years, the effort will re-engage more natural floodplains throughout the state that have been cut off from rivers because of residential, agricultural, and industrial development and earlier efforts to control floods. Taxpayers have paid more than $1.4 billion in flood damage in the area since 1990. The large-scale effort seeks to restore salmon populations, reduce flood hazards, increase agricultural viability, improve water quality, and enhance outdoor recreation.

Mission

The mission of The Nature Conservancy is "to conserve the lands and waters on which all life depends," and the vision is "a world where the diversity of life thrives, and people act to conserve nature for its own sake and its ability to fulfill our needs and enrich our lives." The mission and vision are achieved through the activities and efforts of its members, partners, and employees and guided by a framework called Conservation by Design that provides a systematic approach to determine where to work, what to conserve, what strategies should be used, and how effective these have been (The Nature Conservancy 2014b). The approach outlined below sets out the values by which TNC works:

1. **Integrity Beyond Reproach**: We will meet the highest ethical and professional standards in all of our organizational endeavors, and, in doing so, we hold ourselves accountable to our mission and to the public.
2. **Respect for People, Communities, and Cultures**: Enduring conservation success depends on the active involvement of people and partners whose lives and livelihoods are linked to the natural systems we seek to conserve. We respect the needs, values, and traditions of local communities and cultures, and we forge relationships based on mutual benefit and trust.
3. **Commitment to Diversity**: We recognize that conservation is best advanced by the leadership and contributions of men and women of diverse backgrounds, beliefs, and cultures. We recruit and mentor staff to create an inclusive organization that reflects our global character.
4. **One Conservancy**: Our strength and vitality lie in being one organization working together in local places and across borders to achieve our global mission. We value the collective and collaborative efforts that are so essential to our success.
5. **Tangible, Lasting Results**: We use the best available science, a creative spirit, and a nonconfrontational approach to craft innovative solutions to complex conservation problems at scales that matter and in ways that will endure.

From an increasing position of strength, based on successful fundraising and strong partnerships, TNC has committed to using its resources wisely, to achieving effective conservation outcomes, and to set even higher goals in the face of increasing pressure from, for example, deforestation, overfishing, and carbon emissions (The Nature Conservancy 2014a).

For many years, TNC has seen its workplace as the whole planet and has focused on global challenges to land, water, oceans, cities, and climate. This requires an expanding effort to "protect and restore landscapes, rivers and oceans at an unprecedented scale" and to "transform how we use the world's natural resources by affecting policy and practices locally and globally" and "inspire global action by people who value nature and its role in ensuring thriving communities and dynamic economies" (The Nature Conservancy 2014a).

Ongoing Activities

The need to protect nature is what propelled The Nature Conservancy into existence in 1951. Initially, protection took the form of buying land and setting it aside, using a mix of land purchase and partnership arrangements. This led to the adoption of a suite of diverse actions that extended across entire land and water systems, including areas where people obtained their daily sustenance directly from nature.

TNC has undertaken a large number of wetland-oriented activities including the establishment of freshwater and coastal/marine protected areas and the instigation of conservation and restoration activities. These have included efforts to determine and deliver appropriate environmental flows to rivers and floodplains that had formerly been degraded by the diversion of water for consumptive purposes. This included supporting the 10th international river symposium and international environmental flows conference, held in Brisbane, Australia, September 2007 (Anon 2007). The conference was attended by more than 800 participants who agreed the Brisbane Declaration and affirmed that "Environmental Flows are essential for freshwater ecosystem health and human well-being" and supported previous research conducted by TNC for ensuring the sustainable management of global water resources (Richter 2014).

TNC has also embarked on many wetland-related projects in the coastal and marine environment with one recent initiative directed towards developing methods to restore oyster reefs. These are a natural component of the marine environment that have suffered extensive degradation with an estimated 85% being lost. Given their value for biodiversity and, for example, coastal protection, there are increasing efforts to restore them and have them recognized through the Ramsar Convention on Wetlands (Kasoar et al. 2015). These efforts are leading to community-government partnerships to support the effort needed to repair the damage done in the past and restore at least some of the coastal diversity that previously occurred in many locations around the world, and highlighting the type of work that the TNC has successfully undertaken over many years.

Future Challenges

The challenge for TNC is to continue to advance conservation around the world through working with scientists and collaborators at the local and global scale to leverage results and to confront conservation threats at the largest scale.

Introduction

WetlandCare Australia (WCA) is a leading not-for-profit company that has been working with communities to protect, restore, and promote healthy wetlands since 1991. WetlandCare Australia was founded to undertake practical projects with long-term benefits for wetlands across Australia. The organization implements a broad range of natural resource management and capacity building projects.

WetlandCare Australia has a board of directors who fulfill their role on a voluntary basis. WetlandCare Australia's directors have broad experience, bridging wetland management, conservation, and administration. A staff of 15 covers management and administration, ecology, education and communications, natural resource management, and on-ground work. The organization has five offices on the east coast of Australia from the city of Newcastle in the Hunter Region of New South Wales to Townsville in the wet tropics of Queensland.

As a nonpolitical science-based organization, WetlandCare Australia is dedicated to delivering effective and sustainable outcomes through the use and application of science-based techniques in the restoration and preservation of wetlands. To achieve this, the organization is supported by a Scientific Advisory Panel.

Major Areas of Activity

WetlandCare Australia's conservation strategy sets the organization's goals across five program areas:

Great Barrier Reef Catchments: Improving the health, function, and resilience of aquatic ecosystems across Great Barrier Reef catchments to protect the Reef

Blue Carbon: Mainstreaming a blue carbon agenda into national climate change initiatives

Eastern Wetlands and Water: Improving conservation, management, and sustainable use of wetlands and environmental water across the east coast of Queensland and New South Wales

Australian Wetland Biodiversity: Promoting protection and conservation of Australia's unique wetland flora and fauna

Ramsar Program: Undertaking communication, education, participation, and awareness activities to improve recognition and build capacity for the implementation of the Ramsar Convention in Australia

WetlandCare Australia achieves these goals by working in collaboration with government agencies, landholders, indigenous Australians, community organizations, and business sector. The scope of work the organization undertakes includes:

Wetland classification, assessment, and mapping
Wetland sub-catchment management planning
Wetland restoration and rehabilitation

Wetland protection and conservation
Communications, education, conferences, workshops, seminars, and webinars
Project monitoring, analysis, reporting, and evaluation

Landmark Contributions

WetlandCare Australia's first major project was the restoration of Banrock Station, a 3,400 ha complex of wetlands and native vegetation in South Australia. The project commenced in 1992 when volunteers started a rehabilitation project by installing flow control structures.

In 1994, BRL Hardy Wine Company purchased the property and commenced export production of wine under the Banrock Station label. The company produces over 30 million bottles of wine annually and continued to work in partnership with WetlandCare Australia for almost a decade. The project team manipulated water flow into the Banrock Swamp to reduce the number of introduced European carp, excluded sheep from the swamp, and eradicated rabbits by introducing a control virus. In 1995, the company expanded its rehabilitation program to address management issues on the adjoining Banrock Station Wetland Complex and established a sponsorship and education program to support wise use of wetlands in Australia and internationally.

Through the dedicated work of WetlandCare Australia and Banrock Station Wines, this wetland complex stands as a model for the Ramsar Convention's wise use principle and has now been listed as a Wetland of International Importance under the Ramsar Convention.

Major Projects

WetlandCare Australia has a number of major projects underway.

Coastal 20

WetlandCare Australia is working in partnership with community, government, and industry bodies to rehabilitate 20 wetlands on the east coast of Queensland and New South Wales. These 20 coastal wetlands are biodiversity hotspots and have regional and international significance. They face significant and increasing human and environmental pressures threatening their environmental, cultural, social, and economic values. WetlandCare Australia established regional stakeholder control groups to identify priorities and consult on threat management. The project team undertook ecological assessment of all sites and developed Site Action Plans agreed by the control group. On-ground works include fencing, weed control, feral animal control, community engagement, and education. Coastal 20 is a 2-year program from July 2011 to June 2013 and is funded by the Australian Government through its Caring For Our Country program.

Hunter Estuary Shorebird Protection Program

WetlandCare Australia has a 2-year program of works underway to enhance habitat and control threats to migratory and resident shorebirds in the Hunter Wetlands National Park in New South Wales. The project includes revegetation, weed control, fox control, bird monitoring surveys, and community education. It is being undertaken in collaboration with the NSW National Parks and Wildlife Service, Hunter Bird Observers Club, Hunter-Central Rivers Catchment Management Authority, and Hunter Wetlands Center. The project time frame is July 2011–June 2013 and is funded by the New South Wales State Government through its Environmental Trust.

Maintaining Australia's Biodiversity Hotspots

The Australian Government's Maintaining Australia's Biodiversity Hotspots program used landholder stewardship agreements to support a broad range of management actions on private land tenures nationally. WetlandCare Australia facilitated implementation of the program in the Torrington and Ebor-Dorrigo-Coffs Harbor regions of New South Wales. The organization undertook assessment and preparation of site action plans for numerous properties and managed a competitive bidding process resulting in 23 stewardship agreements. Landholders completed a range of management actions including wetland rehabilitation, weed and pest control, grazing exclusion, and fire management over 3,700 ha of native vegetation with high conservation value.

Australian Wetland Network Secretariat

WetlandCare Australia hosts the Secretariat of the Australian Wetland Network. The network represents over 70 nongovernment organizations (NGOs) working to address wetland conservation across Australia. The Australian Wetland Network coordinates consultation and reporting for the NGO sector in the lead up to the triennial Ramsar Conference of Contracting Parties (COPs) and has attended the past two COPs. The Secretary also serves as the Oceania Coordinator for the World Wetland Network.

Sustainable Wetlands on Coastal Landscapes

WetlandCare Australia (WCA) has been working with coastal NSW Catchment Management Authorities (CMAs) to better understand their wetland priorities. Between 2004 and 2011, WCA has compiled comprehensive wetland mapping for each CMA. The mapping is populated with each wetland's conservation values and potential threats to assist in determining priorities for investment in wetland works.

Further to this, WCA developed and provided CMAs with a decision support database that analyzes conservation value and threat and returns a priority list of wetland complexes for a given area. All CMAs continue to utilize this data in their project and investment planning. The result has been targeted on-ground outcomes for priority wetlands in each region.

Delivering Biodiversity Dividends for the Barratta Creek Catchment

WetlandCare Australia has a project underway to protect and improve management of the Barratta Creek Catchment. This catchment forms the main artery of the Bowling Green Bay wetlands, the only Ramsar site in north Queensland. Barratta Creek is one of the most high-integrity floodplain creek systems on the developed east coast of Queensland. Since the introduction of intensive irrigated agriculture, the creek and associated wetlands have suffered impacts including invasive aquatic and terrestrial weeds, altered fires regimes, and excessive and nutrient-rich tailwater flows. WetlandCare Australia is working with multiple stakeholders to improve biodiversity outcomes through integrated catchment management. The project is supported by the Australian Government's Clean Energy Future's program through its Biodiversity Fund.

Starting in Your Backyard

WetlandCare Australia appreciates that community education and engagement are essential to protect human impacts on wetlands. This program engages residents living in wetland catchments to plan and commit to a program of activities that will reduce the impacts of their home and family on wetlands in their sub-catchment. WetlandCare Australia developed resources and undertook a series of face-to-face "train the trainer" workshops and webinars to build the capacity of local environmental educators throughout New South Wales, Australia. The program was funded by the New South Wales Government through its Environmental Trust.

Further information about WetlandCare Australia can be found at www.wetlandcare.com.au

Wetlands International

91

Jane Madgwick

Contents

Abstract

Wetlands International is the only global nongovernmental organization (NGO) dedicated fully to the wise use of wetlands. It was established in 1995 through bringing together three regional NGOs: International Waterfowl and Wetlands Research Bureau (IWRB), the Asian Wetland Bureau (AWB), and Wetlands for the Americas (WA). Wetlands International is neither a nature conservation organization nor a development one. Instead, Wetlands International connects conservation and development goals. This is because for wetlands, nature and people's well-being are so interdependent. Wetlands International's dual focus is on people and nature, and its broad array of partners and members, both governments and NGOs puts it in a favorable position to bring many different sectors together to tackle the pressing challenges of our time – food and water security, climate change, and biodiversity loss.

Introduction

Wetlands International is the only global NGO dedicated fully to the wise use of wetlands. Wetlands International is neither a nature conservation organization nor a development one. Instead, Wetlands International connects conservation and development goals. This is because for wetlands, nature and people's well-being are so inter-dependent. Our dual focus on people and nature, and our broad array of partners and members, both governments and NGOs, puts us in a favorable position to bring many different sectors together to tackle the pressing challenges of our time – food and water security, climate change, and biodiversity loss.

A Network Organization with Strong Roots in Developing Countries

Wetlands International came about as the result of a close working relation between the International Waterfowl & Wetlands Research Bureau (IWRB) that was created in 1954, the Asian Wetland Bureau (AWB) – initiated as INTERWADER in 1983 – and Wetlands for the Americas (WA) formed in 1989. These three organizations started to work closely together in 1991 and joined to form one single organization in 1995, recognizing that global wetland challenges required a larger, concerted global effort.

Wetlands International is a global network organization working worldwide through, by 2016, 18 offices and through a broad range of partnerships in around 100 countries. All offices share expertise and collaborate to achieve the same set of global goals, using a common set of institutional policies and standards. The head office in the Netherlands guides and supports the work of the network while the regional and national offices are responsible for their programs, staffing, and resources. These offices are established as legal entities in their own countries and are linked to the head office through a Global Network Partnership Agreement that enables collaboration and mutual accountability.

The Association Wetlands International enables governmental and nongovernmental membership to the organization and adopts the long-term strategy of the organization, which is guiding the activities of all offices in the network. The Foundation Wetlands International has the specific to guide and support the office network. Its executive management and the supervision thereof are in the hands of the Management Board and the Supervisory Council, respectively. Members of the Supervisory Council of the Foundation are also members of the Board of the Association.

How Wetlands Can Be Solutions

Securing Water Supplies

As a result of bringing knowledge together at a landscape or basin scale on the values of wetlands such as in supporting water regulation and purification, Wetlands International have been successful in stimulating investments in wetland conservation and restoration, for example to support the sustainability of drinking water and sanitation schemes. In some cases, such as in India and Mali, Wetlands International's evidence has led to reorienting major water infrastructure developments and operations. Wetlands International demonstrate tools and approaches to map wetland values and to connect this with integrated water resource management, working closely with a number of national and local governments. At the global level, Wetlands International are joining forces with major businesses and industry to develop business cases for investing in wetlands as natural water infrastructure to reduce water risks for the long-term.

Reducing Natural Disasters

In working with governments, communities, and private sector partners, Wetlands International place emphasis on reviving wetland ecosystems which grow and adapt to changing environments, rather than physical structures, which cannot. Wetlands International enables local communities to identify the root causes of water-related hazards and to restore and manage wetlands such as along vulnerable coasts, deltas, or floodplains, so as to increase their resilience to severe events. Wetlands International's evidence-base helps to demonstrate to governments that sustaining and restoring wetlands is a cost-effective strategy for disaster risk reduction and climate change adaptation, with strong benefits for poverty reduction and biodiversity conservation.

Meeting the Growing Demand for Food

In the major wetlands where we work, Wetlands International help to integrate wetland values as part of agricultural and fishery systems, including through applying local knowledge. For example in Mali, Wetlands International and its partners are advocating for equitable water sharing and better water governance to sustain fisheries through a participatory approach whereby traditional fisheries management is integrated in river basin-wide food security and environmental governance. In South America, Wetlands International are bringing information to the Roundtable for Sustainable Soy on the trends and impacts of soy cultivation on wetlands and water quality and are working with producers to minimize and mitigate wetland-related threats. Here Wetlands International has also promoted agricultural practices that enhance biodiversity in rice fields. In Indonesia, we work with smallholders to integrate mangroves into shrimp pond design and management, demonstrating how wetland rehabilitation can contribute to livelihood development and food security.

Reducing Greenhouse Gas Emissions

Due to Wetlands International's campaigns, the vital role of wetlands and especially peatlands in storing carbon (more than double that in all the worlds' forests combined) is now recognized by the UN Convention on Climate Change. However, the drainage and degradation of peatlands is causing major greenhouse gas emissions. Wetlands International's projects in Europe and in tropical peatswamp forests have shown the possibilities to halt and reverse this, turning them again into carbon sinks.

Mission, Vision, and Strategy

In 2015, Wetlands International members adopted its 2015–2025 strategy and committed to reviewing its strategic outlook on a regular basis. Every five years, a consultative process with stakeholders and members in all regions helps to set the organization's long-term goals linked to our mission and vision and to establish specific targets associated with a ten year outlook. This helps ensure that the organization remains relevant to the global agenda and the key threats to wetlands/ the key opportunities for wetland conservation and wetland management to contribute to sustainable development.

Wetlands International believes that people's spiritual, physical, cultural, and economic well-being depends on safeguarding and restoring wetlands worldwide. We consider that far greater prominence needs to be given to the conservation and wise use of wetlands as a contribution to sustainable development. We call for improved governance and concerted action by all sectors of society, from global to local levels, to secure wetlands and their range of values and services for current and future generations. More specifically,

Wetlands International's long-term Vision

is a world where wetlands are treasured and nurtured for their beauty, the life they support, and the resources they provide

Wetlands International's Mission

is to sustain and restore wetlands, their resources, and biodiversity

Wetlands International's Goal

is that wetlands are wisely used and restored for the role they play in:

- Improving human well-being and local livelihoods
- Conserving biodiversity
- Sustaining the water cycle
- Reducing climate change and its impacts

Wetlands International's targets and strategic interventions *focus in key geographic areas and on issues where* wetlands make the most difference for people and nature. Our strategic intent for the period 2015–2025 sets out our strategic interventions according the following five target areas:

1. Conserve and restore wetland habitats, sites, and species
2. Conserve and restore peatlands as an integral part of landscape planning and management
3. Conserve and restore wetlands as natural water stores
4. Conserve and restore floodplain systems as blue lifelines in the desert
5. Conserve and restore wetlands as integral part of resilient coastal landscapes

Partnerships

Wetlands International works in partnership with many different organizations on wetland conservation and natural resource management including NGOs, knowledge institutes, business, and industry and international conventions.

The changing governance landscape means that companies are being held more accountable by their stakeholders and consequently must be more transparent in their use of natural resources and impacts on the environment. Companies collaborate with us to improve their environmental and/or social performance in relation to wetlands. We help them to mitigate risks, including physical, regulatory, reputational, and financial risks, as well as to share perspectives and knowledge for innovative solutions where wetlands have a role to play.

Companies like Shell and engineering and dredging firms like Boskalis and Haskoning collaborate with us to help them reduce their environmental impacts and to combine expertise in developing and implementing nature-based engineering solutions. Through our membership of the Dutch-based Ecoshape consortium, we join private sector companies in promoting the building with nature approach, in developing business cases and creating the enabling environment for implementing projects through engaging governments and communities in southern countries, where we are based.

Wetlands International engage and collaborate with water and ecological knowledge institutes in each region, often playing the role of brokering wetland knowledge and technical advice to communities, governments, and private sector players so as to tackle specific challenges. This way of working that combines technical expertise, practical experience, and policy advocacy allows us to scale up successful wetland solutions to have a global impact.

As well as working with a myriad of environmental NGOs and NGO networks globally and in each region, we are close partners with numerous development and humanitarian NGOs and work with their networks in a number of developing countries. For example:

Partners for Sustainable Development: Under the Ecosystem Alliance, we work in partnership with IUCN Netherlands and Both Ends to work in the field (Senegal, Kenya, DRC, Argentina, Indonesia) and at international policy fora to promote the role of ecosystems for people, to green economical trade chains such as soy and palm oil, and to show the importance of wetlands and other ecosystems for climate regulation.

Partners for Disaster Risk Reduction and Climate Change Adaptation: We are member of Partners for Resilience; a partnership between Red Cross (Netherlands), Red Cross Climate Centre, Care (Netherlands), and Cordaid for community – ecosystems based approaches for disaster risk reduction and climate change adaptation. Under the partnership, we lead projects in Mali, India, and are strongly involved in Kenya, Indonesia, Nicaragua, and Guatemala.

Wildfowl and Wetlands Trust

Abstract
Established in 1946 by Sir Peter Scott, one of the most influential conservationists of his time, the Wildfowl & Wetlands Trust (WWT) has grown to become a leading UK-based wetland conservation organization. WWT works across the UK and around the world with a diverse range of partners to create, manage, and restore wetlands. WWT also engages with and works to inspire people, governments, and businesses to take direct action to save wetlands and their wildlife and provide the tools that enable them to do so.

Background

Established in 1946 by Sir Peter Scott, one of the most influential conservationists of his time, the Wildfowl & Wetlands Trust (WWT) has grown to become a leading UK-based wetland conservation organization.

WWT works across the UK and around the world with a diverse range of partners to create, manage, and restore wetlands. WWT also engages with and work to inspire people, governments, and businesses to take direct action to save wetlands and their wildlife and provide the tools that enable them to do so.

WWT and UK's Wetland Reserves

WWT is managing nine wetland reserves and associated land holdings totaling 2,622 ha across the British Isles. This land is of high ecological value, as recognized by the UK, European, or International designations applied to all or parts of our reserves. Six are Wetlands of International Importance as recognized under the Ramsar Convention.

Case Study: An Example of Enhancing Our Reserves Through Habitat Creation at Welney, Norfolk

WWT Welney covers the lower portion of the Ouse Washes in Eastern England, constructed some 300 years ago to drain fenland for agriculture, and holds national, European, and International designations due to its international importance for breeding and wintering birds. However, the Ouse Washes are listed on the Montreux Record of the Ramsar Convention because they are deteriorating due to the impacts of spring/summer flooding with key species declining via subsequent loss of eggs and chicks.

In addition to working with the relevant authorities to try to minimize the impacts of this unseasonal flooding on the Ouse Washes, WWT has also been working to create new areas of habitat adjacent to the Ouse Washes to provide additional and alternative habitat for breeding and wintering birds.

Since 2008, WWT have been creating new wet grassland habitat on former agricultural land. Initial investigations included topographical survey work to ascertain spot heights at key locations and soil analysis to establish the varying depths of peat and underlying clay across the site. Based on this, the design focused on altering the topography to accentuate the natural contours. Transformation into wet grassland was achieved by digging a system of ditches, channels, and scrapes; inserting a waterproof liner; and seeding with native grasses. The sites have been engineered to allow close control of water levels, and grazing by sheep and cattle has been established to manage the grassland, with an electric fence serving the dual purpose of containing the livestock and deterring terrestrial predators.

So far the project has been extremely successful. In addition to up to 500 wigeon *Anas penelope* recorded daily during the first year, snipe *Gallinago gallinago* and jack snipe *Lymnocryptes minimus* have been recorded along with more than 120 lapwing *Vanellus vanellus*, 200 golden plover *Pluvialis apricaria*, and 200 whooper swans *Cygnus cygnus*. In 2011 black-tailed godwits *Limosa limosa* bred successfully – a species whose breeding areas have become highly restricted in recent years and that are at risk of being lost from the Ouse Washes altogether.

Demonstrating Wetland Management and Multifunctionality

WWT works on a variety of wetlands in the UK and internationally that best demonstrate their values and benefits to wildlife and people.

Wetland Treatment Systems

Over the past 20 years, WWT has built-up extensive experience of constructing and managing treatment wetlands at its centers. As of 2013 there are a total of 18 systems across all nine centers designed to tackle a variety of effluents. WWT design systems to mimic natural wetland habitats including pools, marshes, and reedbeds which can support a rich diversity of wetland plants and macroinvertebrates.

They perform a vital function in providing clean water for the wetlands in our reserves and visitor centers but equally also protect the sensitive wetland habitats that water is discharged into, including Strangford Lough and the Severn Estuary, both designated as Wetlands of International Importance.

WWT also undertakes a program of research and development on these systems to ensure they are effectively performing the functions they were designed for and to explore ways to enhance the systems and maximize the full range of benefits that these systems can provide.

WWT has extended this work to include, for example, the design and establishment of a number of treatment systems in Vientiane, Laos and, in the UK, systems for the treatment of waste water from breweries, schools, equine clinics, landfill sites, and farms. WWT are also investigating phosphate cycling under different management options within wetland treatment systems to increase their capacity for phosphate removal and have undertaken innovative research to investigate the benefits of these systems in tackling disease and pathogens.

Our Work Overseas

While being UK-based, WWT also works internationally. The following provides examples of some of the overseas work conducted by WWT.

Cambodia

Since 2010, WWT has been working on a project to protect two wetland sites, Boeung Prek Lapouv (BPL) and Anlung Pring (also known as Kampong Trach) wetlands in the floodplain of the Mekong River in Cambodia. The wetlands are among the last strongholds for the eastern sarus crane *Grus antigone sharpii* and support numerous other threatened wetland species. The sites are also vitally important to local communities, but are under increasing pressure from unsustainable practices.

The main threats to the sites are the exploitation of wildlife, agricultural encroachment, agrochemicals pollution, inappropriate fishing methods, hydrological changes and consequent vegetation changes, and invasive alien plants. WWT is working with three local Cambodian NGOs and in collaboration with the Cambodia Programme of Birdlife International to develop the skills of local conservation groups to better manage the sites and to work with local communities.

The first major success of the project was achieved in January 2011, when Anlung Pring joined BPL in being officially designated by the Cambodian Government as a special protected area for the cranes under the management of the Forestry Administration (FA), in the Ministry of Agriculture, Forestry and Fisheries (MAFF). Since its designation, we have been working with the FA and other governmental and nongovernmental stakeholders to develop a management plan for the site that will identify the key features of the site and prescribe some key management activities.

Beyond the boundaries of the reserves, WWT are also working with local Cambodian NGOs to improve the agricultural and other practices of local communities so that they are less harmful to the wetlands but still provide sustainable livelihoods. WWT are also working to identify alternative livelihood options that can supplement existing options and replace some of the more damaging ones. Among the options being explored are the development of “crane-friendly rice,” ecotourism opportunities, and associated local handicraft products.

Nepal

The wetlands at Koshi Tappu in eastern Nepal are vitally important, not just for Nepal’s last wild water buffalos *Bubalus arnee* and the tens of thousands of waterbirds the wetlands support but also for the people who live there and depend on wetlands for their livelihoods. This dependence results in pressure on wetlands in and around the reserve, so WWT have helped alleviate these pressures by providing sustainable alternatives that support local livelihoods.

In collaboration with Bird Conservation Nepal, WWT has investigated wetland resource use and identified barriers to people obtaining a sustainable livelihood. WWT found several livelihood options that offer sustainable alternatives to current resource use and provided investment and training to enable the poorest most wetland-dependent people locally to benefit from them.

For example:

- Fish farming in ponds dug from agricultural land in the reserve buffer zone provides a good alternative to the capture of wild fish for local fish-dependent people.
- Weaving mats using *Typha* offers an alternative to fishing as a livelihood, enabling women in particular to generate an income.

WWT has also found two good uses for invasive nonnative plants. These both support local livelihoods and provide an incentive for people to remove them from waterbodies:

- Using water hyacinth *Eichhorniacrassipes* to make compost reduces the need to purchase chemical fertilizers.
- Charcoal made from invasive *Ipomoea* and *Lantana* is made into briquettes. These provide a smokeless fuel which is more efficient and cheaper than firewood and reduces demand for animal manure for fuel (thus increasing the amount available as fertilizer on farmland).

A cost-benefit analysis of the three livelihood alternatives that provide an income (fish farming, mat weaving, and briquette making) showed that these sustainable options give excellent returns per unit area of land used compared to conventional crop-growing (multiple cropping of rice, maize, wheat, and fodder).

Work is ongoing to encourage the uptake of these livelihoods and to inform the revision of the site management plan by the Department of National Parks and Wildlife Conservation. In order to support this we have produced a set of wetland management guidelines and are continuing to work with Bird Conservation Nepal to monitor the situation and measure the benefits that uptake of livelihood options bring to both people and biodiversity, and to determine whether further conservation and development work is necessary.

Health in Wetlands

WWT has a long history and international reputation in wildlife health and has contributed to the Ramsar Convention's work on healthy wetlands and healthy people. One of the most important outputs of this work was the crafting, with colleagues from other organizations, of Resolution XI.12 on an ecosystem approach to health. The Resolution, which was adopted by the 163 contracting parties to Convention in the summer of 2012, explicitly recognizes the interconnectivity of health of all life within wetlands and how maintenance of well-functioning wetlands promotes health across these sectors.

As a resource to help wetland managers achieve health in wetlands, the Ramsar Wetland Disease Manual (Cromie et al. 2012), produced by WWT for Ramsar's Scientific and Technical Review Panel, was launched in 2012 at the same time as the

Resolution. The Manual recognizes the importance of the role of wetland managers in the prevention of health problems and represents a practical resource for this key stakeholder group as well as policy makers. It provides an overview and the principles of animal health and disease management, specific and generic practices for preventing and controlling diseases in wetlands, user-friendly factsheets of a wide range of priority animal diseases of wetlands, and case studies. Although focused on wetlands, many of the principles and practices are appropriate for other habitats.

Future Challenges?

Throughout history wetlands have suffered from being been misunderstood and undervalued, leading to more rapid loss and degradation than most other habitat types. Those wetlands that remain today are faced with ever increasing pressures, and their piecemeal degradation and destruction continues. WWT has identified the following particularly significant threats to wetlands:

- Direct destruction of wetlands
- Overexploitation of natural resources
- Pollution
- Invasive species
- Disturbance
- Flow modification
- Disease

These well-known and long-standing challenges are now also being exacerbated by new threats and drivers such as climate change and unsustainable (and increasingly globalized) patterns of consumption of natural resources. A further complicating factor for wetlands is that, due to their position within the landscape, wetlands are often the "receivers" of multiple threats acting in combination and often originating from locations far removed from the wetlands themselves.

Fundamentally, many of these threats have their origin in the lack of understanding and appreciation of the importance and functions of wetland ecosystems. Changing this perception is, and will continue to be, at the heart of WWT's mission.

World Wetland Network

93

Chris Rostron

Contents

Abstract

The World Wetland Network (WWN) acts as a support network for relatively small NGOs engaged in wetland conservation. This may not be their main activity, but broadens involvement of NGOs or CSOs (civil society groups) that recognize the importance of wetlands not only for biodiversity, but also for human and economic well-being. WWN aims to bridge the gap between multilateral environmental agreements and the NGOs that deliver wetland work at ground level. Although the Ramsar International Organization Partners (WWF, IUCN, BirdLife International, Wetlands International, IMWI, and WWT) are already an integral part of the Ramsar structure, they represent a distinct international focus. WWN works to ensure that the interests of smaller NGOs are better integrated, raising their profile as significant deliverers of wetland conservation on the ground.

Introduction

The World Wetland Network (WWN) acts as a support network for relatively small NGOs engaged in wetland conservation. This may not be their main activity, but broadens involvement of NGOs or CSOs (civil society groups) that recognize the importance of wetlands not only for biodiversity, but also for human and economic well-being. WWN aims to bridge the gap between multilateral environmental agreements and the NGOs that deliver wetland work at ground level. Although the Ramsar IOPs (international organization partners), such as WWF, IUCN, BirdLife, Wetlands International, IMWI and WWT, are already an integral part of the Ramsar structure, they represent a distinct international focus. WWN works to ensure that the interests of smaller NGOs are better integrated, raising their profile as significant deliverers of wetland conservation on the ground.

Origins

WWN arose from a perceived need for better organization among NGOs at the Ramsar Conference of the Parties (COP10 in Changwon, Repbulic of Korea, in 2008). NGOs had been active at previous COPs and often achieved input to the COP proceedings, formally during the plenary and work groups, informally behind the scenes, or through actions outside the COP proceedings. However, NGO representatives felt that their sector could work more effectively if it adopted a more structured approach, offering support and coordination for the diverse range of groups that attend the Ramsar COPs, or that work to deliver wetland conservation.

The network is not a formally constituted group, but is run by a group of NGO representatives, the WWN Committee, put forward at the Ramsar COP10, and hosted by the Wildfowl and Wetlands Trust, UK (WWT). WWN had nearly 2000 members as of 2012, many of whom signed up as part of the process of voting for their wetlands during the two rounds of the Globe Awards. Membership is free and open to all CSO groups and individuals that are actively engaged in wetland conservation.

The key aims of the WWN are as follows:

(a) Facilitate and coordinate the involvement of wetland NGOs at every Ramsar COP, particularly through the international NGO meeting, and help influence similar Multi-lateral Environmental Agreements.
(b) Raise the profile of wetland NGOs and their role in the local delivery of international wetland conservation agreements.
(c) Create an international platform to share knowledge and spread messages about the best practices for wetland conservation and wise use.
(d) Take positive action to support good wetland management, and offer support to local NGOs in their work to protect internationally important wetlands.

Actions at the Ramsar COPs

Every three years, the Ramsar Convention holds a Conference of the Parties (COP), with 2012 seeing the 11th COP. At COP10, 2008, in the Republic of Korea, an International Wetland Conference was held, which resulted in the establishment of the WWN. The following COP11 was the first conference that saw WWN playing a really active role. Preparation for the Ramsar COP11 started well in advance, recognizing the need of smaller NGOs to understand how Ramsar COPs function and the opportunities for NGO involvement during the process. A preparatory meeting was held at CENEAM, Segovia, Spain, bringing together representatives of the WWN committee and some of the IOPs, who are well experienced in previous COPs. The meeting involved an initial review of the voting for the Wetland Globes, a detailed review of the draft resolutions that were proposed for discussion at the COP, and planning for NGO engagement at COP11, including the structure of the international NGO meeting to be held at the start of the COP.

Immediately before the start of the COP11, the international NGO conference was convened, with speakers from the Secretariat and NGO representatives that had been involved heavily in the previous COPs. The event brought NGO delegates together to meet and discuss issues, provided guidance on how to engage during the COP, carried out work on identifying which Draft Resolutions should be of highest priority for engagement, and prepared the opening NGO statement for the COP, read out by a Romanian NGO representative to Ramsar delegates during the opening plenary. Those NGOs attending prepared a closing statement which the WWN Chair read out during the closing ceremony. This gave support from civil society, but also reiterated the need to recognize NGO input at both the COP and within Ramsar member countries.

Wetland Globe Awards

The Wetland Globe Awards is an initiative developed by WWN to draw attention to the role of civil society in wetland management, highlight best practice through case studies, draw attention to wetlands under threat, and offer an opportunity for civil society to register its opinion on local wetlands at an international level. The awards are made for the wetland itself, not to any specific organization, emphasizing the concept that wetlands need all sectors (governmental, business, and civil society) to work together to protect them.

Lake Natron received the Blue Globe award at CBD COP10 in 2010, for not allowing development of a soda ash plant, which would have severely compromised the breeding ground of the lesser flamingo. Shortly after, the development was proposed again, but the Globe Award was used as one of the reasons in the campaign against it. The proposal was eventually turned down again.

Future Challenges

WWN continues to have regular meetings of the committee, and subregional representatives are active across the globe to varying degrees. WWN will also continue to run the Wetland Globe Awards and has ambitions to create a civil society monitoring tool for wetlands. The challenge is to secure sustainable funding to allow development of these ideas. WWN is not an independently constituted group, but hosted at WWT, and therefore cannot fund-raise on its own. Consequently, the challenge is to get enough activity and resources to attract funding, and then justify constitution and independence.

94 World Wide Fund for Nature (WWF)

C. Max Finlayson

Contents

Abstract

The World Wide Fund for Nature (WWF) is an international nongovernmental organization that was founded in 1961 and is based in Switzerland. It was formerly called the World Wildlife Fund, which remains the official name in Canada and the United States, and was changed in 1986 to better reflect the scope of its activities. In 2001 the original acronym of WWF became its one, global name. Its logo is the highly recognizable black-and-white panda that has come to be seen as a symbol for the conservation movement as a whole. Ongoing conservation activities include those that support wetlands and their species, as well as specific initiatives such as the Living Planet Index.

Introduction

The World Wide Fund for Nature (WWF) is an international nongovernmental organization that was founded in 1961 and is based in Gland, Switzerland. It was formerly called the World Wildlife Fund, which remains the official name in Canada and the United States, and was changed in 1986 to better reflect the scope of its activities. In 2001 the original acronym of WWF became its one, global name. Its logo is the highly recognizable black-and-white panda that has since come to be seen as a symbol for the conservation movement as a whole. Information on the organization and its many activities is available through its annual reports (see WWF 2015) and web pages (http://wwf.panda.org), including those for its offices around the world. This information forms the basis of the text that follows.

WWF is now one of the world's largest conservation organizations with over five million supporters. It has invested in excess of US$1 billion in more than 12,000 projects since 1985 and currently has conservation and environmental projects in more than 100 countries. These projects contribute to the general goal of finding a balance between biodiversity and the demands that humans place on natural resources, including biodiversity.

It is an independent foundation registered under Swiss law and is governed by a board of trustees under an international president. More than half of its funding comes from individuals and bequests, with the remainder from governmental sources and corporations. An international secretariat is based in Gland, Switzerland, with the role of leading and coordinating the network of WWF offices around the world through the development of policies and priorities, partnerships, and international campaigns. The network of offices comprises those that raise funds and work autonomously and those that work under the direction of one of the other offices.

All offices undertake conservation work, including practical field projects, scientific research, advising local and national governments on environmental policy, promoting environmental education, and raising awareness of environmental issues. Those that work independently also contribute funding to WWF's global conservation program. All offices contribute to an enormous pool of environmental expertise and knowledge.

History

WWF was formed by a small group of scientists and advertising and public relations experts committed to establishing an international organization to raise funds for conservation. In April 1961, they signed a declaration entitled "We Must Save the World's Wild Life" that became known as the *Morges Manifesto*. Its operations were based in Morges, Switzerland, where IUCN was then based. Offices were established in different countries and National Appeals launched, with two-thirds of the funds they raised being sent to the international secretariat and the remainder retained for their own conservation projects. Its work was based on the best available science and included educational activities as well as wildlife surveys and antipoaching projects. Many of the animals and habitats that featured in the early work of WWF have assumed an iconic status and still feature. This includes the assistance provided to establish the Charles Darwin Foundation Research Station in the Galápagos Islands and in 1998 the Galápagos Marine Reserve. It also included support for the purchase of land in the Guadalquivir Delta marshes in Spain that later became the Coto Doñana National Park – an important site for migratory water birds and nowadays an internationally important wetland (Ramsar site).

As the success of individual projects became known, WWF encouraged the development and implementation of a more comprehensive conservation effort for entire biomes as well as species across their range. This included support for the development of the Ramsar Convention on Wetlands that was signed in 1971. The Convention addressed both the wise use and conservation of wetlands, and through its wise use, provisions (Finlayson et al. 2011) became a forerunner of the sustainable development principles that were being developed by WWF and its partners.

Despite the impressive effort and conservation successes through an expanded global presence, the organization realized that parks and crisis-led conservation efforts were not enough. This led to a greater emphasis on the importance of conservation for people and the integration of conservation with development. This led to the World Conservation Strategy (IUCN et al. 1980) which integrated conservation and the sustainable use of natural resources and explained conservation objectives in terms of the benefits to people. By the 1990s, the link between biodiversity, human activities, and well-being and livelihoods had become more widely accepted and are now explicitly included in WWF's mission and operating procedures that focus attention on ecoregions and with increased engagement with business and new partnerships in support of sustainable development.

WWF continued to support international efforts and was instrumental in establishing the Convention on Biological Diversity (CBD) in 1992. Since then, WWF has continued to support the Convention and lobby for specific outcomes and programs to address the conservation and use of biodiversity. In 2002, the Convention adopted a program of work to significantly reduce the rate of biodiversity loss by 2010. It further successfully lobbied for a program of work on protected areas, including concrete targets and timelines. The outcomes of such work are presented in many fora and publications, including those for protected areas, including for freshwater systems (see Pittock et al. 2014).

Mission

WWF's mission is to stop the degradation of the planet's natural environment and to build a future in which humans live in harmony with nature, by conserving the world's biological diversity, ensuring that the use of renewable natural resources is sustainable, and promoting the reduction of pollution and wasteful consumption.

In response to this mission, WWF has directed its work toward reducing the impact of people on the biological diversity of deserts, forests, freshwater, marine, and mountain ecosystems, as well as in specific places. The latter have been identified on the basis of the best available scientific evidence as important for irreplaceable and threatened biodiversity or representing an opportunity to conserve a representative and large example of a specific ecosystem. Over time, the focus has moved away from localized efforts to conserve single species and individual habitats to an ambitious and strategic approach for global conservation and sustainable development.

Ongoing Activities

WWF has from its founding worked with partners, including UN organizations, development agencies, and other nongovernmental organizations, as well as business and industrial enterprises. The latter have become increasingly important in some of WWF's conservation projects, although at times this courts controversy. By working with private businesses, WWF is seeking to change behavior and achieve conservation results that would not be possible otherwise.

Given restraints on resources and the critical nature of many conservation issues, WWF has focused its considerable efforts on a number of Global Initiatives. These are seen as visionary and large-scale efforts with the potential for broad positive impacts across species and ecoregions and form the centerpieces of a strategic conservation plan. For WWF this was based upon an analysis of the global distribution of biodiversity resulting in a map now known as the Global 200 (Olson and Dinerstein 2002). The Global 200 began with WWF asking the question: "if we wish to conserve biodiversity, where should we be investing our precious conservation funds?" It was an exercise in prioritization, recognizing that if the available resources were spread too thinly they could not achieve the desired result; then how should they be focused?

WWF's focus is very much on the Earth's most special places with the expectation that it is possible to conserve most of life on Earth by protecting the most exceptional ecosystems and habitats. This includes places that are particularly rich in biodiversity, those that support unique animals and plants, and those that are like no other. Priority places include deserts, forests, freshwater, marine, and mountains. Endangered species are also addressed, including flagship and footprint-impacted species. Flagship species are iconic animals that provide a focus for raising awareness and stimulating action and funding for broader conservation efforts. Footprint-impacted species are those whose populations are primarily threatened because of unsustainable hunting, logging or fishing. It is expected that by strategically focusing efforts on these species, there will be positive outcomes for the many other species that share their habitats and/or are vulnerable to the same threats. They have also chosen five priority areas to reduce humanity's ecological footprint – the amount of land and natural resources needed to supply our food, water, fiber, and timber and to absorb our CO_2 emissions. These are carbon, energy, and climate (energy use, impact of forest loss, and the need for a new global policy on climate change), sustainable cities (transition of cities for sustainable development), farming (food, fiber, grazing, aquaculture, and biofuels), fishing (overfishing, illegal and unregulated fishing, bycatch, and poor management and procurement), forestry (timber, paper, pulp, and fuel wood), and water (dams, irrigation, and drinking supplies).

In among the many projects that have been successful, the implementation of the Living Planet Report that was first published in 1998 has resulted in the production of an important publication with information on the conservation status of vertebrate animals and an estimate of the human footprint. This information is produced as the Living Planet Index and the Ecological Footprint (WWF 2014). The former shows that over the period 1970–2010 approximately 50% of vertebrate population for which data were obtained are declining, while at the same time the ecological footprint of humans has more than doubled. The freshwater index shows the greatest decline of any of the biome-based indices with an average decline of 76% in the monitored populations between 1970 and 2010. The ecological footprint shows that 1.5 Earths are now required to meet the demands humanity makes on nature each year.

In response to these trends, WWF continues to provide a lot of support for the aims and goals of the Ramsar Convention on Wetlands. This includes through the formal role of an International Organization Partner and participation in the governance and technical bodies of the Convention. It has continued its efforts to support countries to join the Convention and to nominate and manage wetlands of international importance. In this manner, it is both building on its history in helping to establish the Convention and extending its partnerships and approaches to reduce the degradation of the planet's natural environment and to build a future in which humans live in harmony with nature.

Wetland Law and Policy: Overview

95

C. Max Finlayson and Royal C. Gardner

Contents

Abstract

The term "wetland law and policy" refers to the legally related rules developed by governments that pertain to activities that affect wetlands. When used in a general sense, wetland law and policy encompasses a broad range of instruments, including "*. . .legislation, such as statutes, acts, decrees, and ordinances; regulations and other rules promulgated by agencies that have the force of law; and policies, which depending on the jurisdiction may also have the force of the law or may merely provide principles or rules that guide a decision-making process.*" It can also include judicial decisions that apply or interpret the legislation, regulations, and policies. Wetland law and policy may govern activities that have the potential to harm wetlands as well as activities that may benefit wetlands and the ecosystem services they provide.

Introduction

The term "wetland law and policy" refers to the legally related rules developed by governments that pertain to activities that affect wetlands. When used in a general sense, wetland law and policy encompasses a broad range of instruments, including "*. . .legislation, such as statutes, acts, decrees, and ordinances; regulations and other rules promulgated by agencies that have the force of law; and policies, which depending on the jurisdiction may also have the force of the law or may merely provide principles or rules that guide a decision-making process*" (Gardner et al. 2012). It can also include judicial decisions that apply or interpret the legislation, regulations, and policies. Wetland law and policy may govern activities that have the potential to harm wetlands as well as activities that may benefit wetlands and the ecosystem services they provide.

Law, Policy, and Wetlands

The United States experience with its legal definition of the term "wetland" provides an example of the differences between statutes, regulations, and guidance documents. As Fig. 1 indicates, the United States Congress (the national legislature) enacted the Clean Water Act, a statute that regulates activities in "waters of the United States." The agencies charged with implementing the Clean Water Act then issued a regulation defining "water of the United States" to include wetlands. Further, more detailed technical guidance was developed through wetland delineation manuals, which are used to determine the boundaries between a wetland and an upland. The statute and regulations are law in the sense that they are binding and have the "force of law." The delineation manuals, on the other hand, are more akin to policy or guidance documents, which do not have the force of law. Nevertheless, application of such guidance can have legal implications.

While wetland laws and policies can differ significantly from jurisdiction to jurisdiction, they can generally be categorized as regulatory or nonregulatory approaches (Gardner 2003).

- A regulatory approach suggests that government permission is needed before a proposed action that could affect wetlands moves forward. In some cases, violators may be subject to administrative, civil, or even criminal penalties.
- A nonregulatory approach establishes incentives (financial or otherwise) that encourage voluntary actions to conserve or protect wetlands.

Regulatory and nonregulatory wetland laws and policies can take many different forms. Many variations exist in different countries, shaped by their particular governance and legal systems, as well as local customs and practices. The

Statute Clean Water Act (enacted by Congress)	33 U.S.C. §1344	Section404: Corps of Engineers may issue permits for discharge of dredged or fill material into the "navigable waters"
	33 U.S.C. §1362	Section502: The term "navigable waters" is defined as "the waters of the United States, including the territorial seas"
	33 C.F.R. §328.3(a)(3)	Definition of "waters of the United States" includes"wetlands... the use, degradation or destruction of which could affect interstate or foreign commerce"
Regulations Corps of Engineers Regulatory Program (promulgated through notice-and-commen trule making and codified in the Code of Federal Regulations)	33 C.F.R. §328.3(a)(7)	Definition of "waters of the United States" includes"[w]etlands adjacent to [other] waters [of the United States]"
	33 C.F.R. §328.3(b)	"Wetlands" is defined as "those areas that are inundated or saturated by surface or ground water at a frequency and duration sufficient to support... a prevalence of vegetation typically adapted for life in saturated soil conditions. Wetlands generally include swamps, marshes, bogs, and similar areas."
Guidance Corps of Engineers Regulatory Program (may not be subjected to notice-and-comment rule making and is not codified in the Code of Federal Regulations)	Technical Report Y-87-1, U.S. Army Corps of Engineers Waterways Experiment Station	Wetland Delineation Manual detailing indicators for wetland hydrology, hydrophytic vegetation, and hydric soils
	Regional Supplements	Regional supplements issued (or in process of being issued) for: Alaska; Arid West; Atlantic and Gulf Coast; Great Plains; Western Mountains; Mid-West; Caribbean Islands; and Northcentral and Northeast

Fig. 1 The interplay of statutes, regulations, and technical guidance in the United States (From *Lawyers, Swamps, and Money*, by Royal C. Gardner. Copyright © 2011 Royal C. Gardner. Reproduced by permission of Island Press, Washington, D.C.)

importance of the latter should not be underestimated, whether dealing with traditional access or property rights of local or indigenous communities or with more contemporary commercial enterprises.

Regulatory Approaches in Application of Wetland Law and Policy

In its simplest form, a regulatory approach involves a prohibition and a permit system. An activity, such as filling in a wetland, is prohibited unless the appropriate government agency or official grants permission for the activity to proceed. Often, an environmental impact assessment or study is required prior to the permit decision.

Ideally, an environmental impact assessment promotes informed decision-making. Such studies will typically consider the environmental impacts of the proposed activity, any feasible alternatives to the proposed activity, and the environmental impacts of those alternative courses of action. A "no action" or "status quo" (also known in the UK and elsewhere as "do nothing") option is usually included in the assessment, often serving as a counterfactual. In the wetland permit context, the "no action" alternative would be the denial of a permit, in which case the proposed activity could not legally proceed.

The use of environmental impact assessments became prevalent in the United States after the enactment of the National Environmental Policy Act (NEPA) in 1970. NEPA is a broad "stop and think" statute. It requires an environmental study prior to federal agencies taking certain actions. NEPA applies both to government projects that a federal agency itself performs (e.g., a dam construction project) and to private projects that require a federal permit (e.g., the construction of a housing project on privately owned wetlands). The use of environmental assessments is now a common tool throughout the world (Wood 2003) and a recommended practice by the Ramsar Convention on Wetlands that also encourages the adoption of Strategic Environmental Assessment to ensure a broader consideration of the multiplicity of activities that can impact adversely on wetlands (Ramsar Convention Conference of the Parties 2008).

It is important to note that laws and policies that require environmental impact assessments are frequently *process-focused*. In other words, the legal instrument dictates that a particular process must be followed to encourage informed decision-making. The resulting environmental study, while educating decision-makers about impacts and alternatives, does not necessarily dictate a result. A governmental agency or official may still choose an alternative that is harmful to the environment and wetlands. However, it needs to be a decision made with the awareness of the environmental and wider consequent socio-economic consequences. It is also important to note that although environmental impact assessment may be required by law, the recommendations and conclusions in these studies often have no legal effect by themselves. To be legally binding, the recommendations and conclusions should be incorporated into the terms and conditions of a permit authorizing an activity or project and potentially subject to compliance measures.

The requirement for permits for activities affecting wetlands may flow from a wetland-specific law or policy. For example, Uganda has a specific National Wetland Policy that encourages the avoidance of wetland impacts, stating that there will be "*. . .no drainage of wetlands unless more important environmental management requirements supersede*" and "*. . .only those uses that have been proved to be nondestructive to wetlands and their surroundings will be allowed and/or encouraged.*" In other cases, permit requirements for wetland impacts are the result of broader water-related laws (such as the Clean Water Act in the United States or the Water Framework Directive in the European Union). Also common are permit requirements of general environment or conservation and biodiversity-related laws and policies that encompass wetlands, as well as those that are targeted

mainly at conserving resources such as fisheries or water. The importance of the latter should not be underestimated, as many wetlands are under private ownership and used by individuals or communities for commercial or subsistence purposes.

Many permit schemes call for regulatory agencies to use some type of avoid-mitigate-compensate framework. Under such a framework, a wetland law or policy may express a preference that adverse wetland impacts be avoided to the extent feasible. Table 1 provides an example of the sources of the “avoidance” step or alternative analysis in the United States, ranging from the general statutory authority to the more detailed regulations and policy documents.

If wetland impacts cannot be avoided, the impacts need to be mitigated or minimized. Any remaining impacts then should be compensated for, that is, offset by wetland restoration, enhancement, creation, or preservation projects. The importance of wetland restoration has been recognized and is now widely practiced in many countries whether through regulatory mechanisms associated with permits and compliance arrangements or through community effort, such as the considerable involvement of nongovernmental and community-based organizations in wetland restoration in northern America and parts of Europe.

Offset mechanisms in a permit context can take several different forms. The simplest approach is where the permittee itself does the offset project or hires an environmental consultant or engineer to carry out the project. Many studies have found that such “permittee-responsible” offsets have not achieved the desired ecological results (National Research Council 2001). Accordingly, some countries have turned to “wetland banking” or “wetland mitigation banking” to provide offsets to wetland impacts. As described in Ramsar Resolution XI.9 (2012), wetland banking occurs where “*. . . a site owner generates compensation credits through the restoration, enhancement, creation and/or preservation of wetlands. The amount of credits generated is based on the ecological improvements at the site. Credits are* *then sold to developers to offset adverse wetland impacts to the same type of habitat elsewhere*." Wetland banking requires a well-developed legal system, relying on legal rules related to "*. . . property rights (e.g., conservation easements), enforcement authority, and commercial and financial law (e.g., letters of credit, performance bonds, endowment accounts)*" (Gardner et al., in press). A third offset mechanism is called "fee mitigation" or "in-lieu fee mitigation" where a permittee would pay money into a fund which would then finance offset projects.

Many regulatory schemes contain enforcement provisions. If a developer fills a wetland without obtaining the necessary permit, it could be subject to administrative or judicial fines and penalties and even be ordered to restore the site. In rare cases, violators have been subjected to criminal prosecution (Gardner 2011). Permittees may also be subject to enforcement actions if they do not comply with the conditions of the permit. An enforcement action is typically initiated by a government agency or ministry. In some countries, such as the United States, individuals or NGOs may bring a "citizen suit" and sue an alleged violator directly if the government has failed to do so.

The denial of a wetland permit also has legal consequences and may affect property or use rights. In countries where wetlands can be privately owned, a property owner that has been denied a permit may claim that its property rights have been interfered with to such an extent that the government should provide financial compensation. In such cases, the property owner would file an administrative or judicial action to seek such payments.

Nonregulatory Approaches

In addition to the regulatory approaches outlined above, wetland laws and policies may take a nonregulatory approach. Sometimes these approaches are formally reflected in national policies, such as those enacted by Australia and Canada. These are based on a willingness to support common targets or activities, at times with substantive incentives, such as the provision of funding for management and restoration activities or capacity building. The abovementioned national policies are examples of nonregulatory approaches in response to the recommendations from the Ramsar Convention on Wetlands for Contracting Parties (countries) to develop and implement policies for the wise use of wetlands. The success of such measures is debatable as, for example, only 47% of the 160 Contracting Parties to the Convention had reported that they had taken steps to develop National Wetland Policies and incorporate wetlands into a national strategy for sustainable development (Finlayson 2012).

Finlayson (2012) further reported that fewer than half of the Contracting Parties reported activities in response to many of the goals and strategies contained in the Convention's Strategic Plan. As many of the decisions taken by the Convention are not binding, this may not be a surprising outcome. However, it does beg a question about the extent to which such nonregulatory approaches are effective. Finlayson et al. (2011) also considered whether nonregulatory approaches at an international level could be effective and concluded that "*Initial findings indicate that those countries that report better implementation are also reporting that their* *wetlands are in a relatively better state. In particular, this appears to be the case for countries that have established national policy/legislative frameworks and that are undertaking a wide range of implementation activities both nationally and on-the-ground.*"

Canada, the United States, and the countries in the European Union have many nonregulatory programs that encourage wetland restoration (Gardner 2003). In some cases, farmers are paid to convert agricultural lands back to wetlands. For example, in the United States, the Wetlands Reserve Program, administered by the Department of Agriculture offers farmers to voluntarily protect and restore wetlands. The level of cost-sharing payments depends on the duration of the protective measures. More than 11,000 landowners have participated in the Wetlands Reserve Program, covering more than 930,000 hectares of land (US Department of Agriculture 2011).

Another nonregulatory approach involves tax incentives. In Canada, the province of Ontario has a Conservation Land Tax Incentive Program that encourages the protection of provincially important wetlands. Property enrolled in the program can be exempt from property taxes.

In recent years, there has been wider recognition of the importance of traditional access and customs of indigenous peoples, such as in northern Australia where land rights and traditional ecological knowledge have supported both regulatory and nonregulatory approaches for managing wetlands (Finlayson et al. 1998). The importance of local customs and practices has also been formally recognized through the global Strategic Plan for Biodiversity 2011–2020 and the Aichi Targets (Convention on Biological Diversity Conference of the Parties 2010) which includes a target whereby "*By 2020, the traditional knowledge, innovations and practices of Indigenous and local communities relevant for the conservation and sustainable use of biodiversity, and their customary use of biological resources, as respected, subject to national legislation and relevant international obligations, and fully integrated and reflected in the implementation of the Convention with the full and effective participation of Indigenous and local communities, at all relevant levels.*" This is an important target but, like the 2010 Biodiversity target that was not met (Armenteras and Finlayson 2012), is also nonbinding and dependent on nonbinding responses by national governments.

The nonbinding nature of approaches to encourage the effective management of wetlands may allow flexibility and encourage sectors and individuals to collaborate and seek joint solutions. This is particularly important when resources for implementing policies are not available or where [potential] policies may be seen as intrusive, inflexible, or practically unenforceable. The importance of community-based or nongovernmental organizations in supporting the delivery of nonregulatory approaches is widely recognized and, in some instances, has provided the basis for bringing governments and others together to explore and develop joint outcomes. At an international level, the development of the Ramsar Convention is an explicit example whereby the development of an intergovernmental treaty was spearheaded by nongovernmental organizations. Such organizations continue to play an important role in developing policy and responding to recommendations made by governments through the Convention processes.

The Influence of International Law on Domestic Wetland Law and Policy

Although wetland laws and policies are primarily domestic-based (i.e., nationally or locally based), international legal instruments, primarily through conventions and other agreements among countries, can influence these laws and policies. However, in practice, the legal effect of a convention within a particular country varies widely. The extent to which a convention or treaty applies directly in a country depends in part on whether that country subscribes to a monist or dualist approach to international law (Bruch 2006).

A monist approach generally means that "international law is part of the domestic law of the country" (Bruch 2006). This means, in some countries, that an international convention is viewed as controlling or overriding domestic or national law. In other monist countries, an international convention has the same authority as a statute or legislative decree, while in other countries domestic laws trump conventions. Despite these variations within monist countries, an important distinction is when such a country joins a convention that agreement "is directly applicable" if its provisions are sufficiently clear.

In contrast, countries that have a dualist approach to international law consider international law to be separate from domestic law. Consequently, an international legal instrument, such as the Ramsar Convention, does not immediately affect a dualist country's domestic legislation. In order for the convention to apply within that jurisdiction, the dualist country would have to enact implementing legislation, also known as the "act of transformation" (Bruch 2006).

In very broad terms, civil law countries follow the monist approach, while common law countries use the dualist approach. Some countries, such as the United States and New Zealand, follow a mixed approach (Shelton 2011).

Challenges

It is important to note that legal regimes, whether regulatory or voluntary, do not necessarily translate to wetland conservation on the ground. Wetland law and policy is often only effective if there is effective enforcement, which requires appropriate investment in administrative entities empowered to protect wetlands.

It is also important to recognize that wetland laws and policies need to be suited to specific socio-economic contexts. For example, an approach that works in urban areas in the United States may not be appropriate for rural KwaZulu-Natal where different (often informal) governance systems operate.

Finally, a mix of regulatory and nonregulatory approaches is required for effective wetland conservation. Sometimes, a nonregulatory approach is more effective than a regulatory approach, especially if the stakeholders (e.g., farmers in the United States) are particularly resistant to or suspicious of traditional regulatory mechanisms. Laws and policies should be developed as part of a coherent broader policy toolkit serving as "societal levers" (sensu Everard et al. 2014), shaping local decisions and actions, including *inter alia*: top-down statutory regulation and levies, bottom-up initiatives including quality assurance networks or community-based partnerships, formal incentives, common law, voluntary market-based schemes such as "payments for ecosystem services," offsetting, and informal agreements and protocols.

National Wetland Policies: The Basics

96

Royal C. Gardner

Contents

Abstract

A national wetland policy is a published governmental statement that articulates how wetland conservation and management is to be achieved within a particular jurisdiction. The policy may be contained in a legally binding instrument, such as a statute or decree, or it may be contained in a nonlegally binding aspirational document. Ideally, a national wetland policy includes assessable goals, timelines for achievement of those goals, roles and responsibilities of various actors, and budget commitments that provide adequate financial support for implementation.

or it may be contained in a non-legally binding aspirational document. Ideally, a national wetland policy includes assessable goals, timelines for achievement of those goals, roles and responsibilities of various actors, and budget commitments that provide adequate financial support for implementation (Ramsar Convention Secretariat 2010).

One driver for national wetland policies is the Ramsar Convention. Countries that join the Convention (known as Contracting Parties) undertake, inter alia, a commitment for the wise use of wetlands within their territories. A national wetland policy is considered a key feature for satisfying a Contracting Party's wise use obligation. Indeed, the annex to Ramsar Recommendation 4.10 (1990) stated that "[i]*t is desirable in the long term that all Contracting Parties should have comprehensive national wetland policies*, [which] *should as far as possible address all problems and activities related to wetlands within a national context.*"

The Ramsar Convention's Strategic Plan for 2009–2015 further emphasized the importance of national wetland policies, calling for them "*. . .or equivalent instruments* [to be] *fully in place alongside and integrated with other strategic and planning processes by all Parties, including poverty eradication strategies, water resources management and water efficiency plans, coastal and marine resource management plans, national forest programmes, national strategies for sustainable development, and national policies or measures on agriculture*" (Ramsar Convention Conference of the Parties 2012).

Ramsar Resolution VII.6 (1999) offers guidance on developing and implementing national wetland policies. The policy-making process itself can be a mechanism for building consensus through the participation of stakeholders. Indeed, "*. . .the process used to develop the Policy is its greatest source of strength, particularly when dealing with broad issues and multiple stakeholder interests*" (Ramsar Convention Secretariat 2010).

Ramsar Contracting Parties must report each triennium the status of national wetland policies within their jurisdictions. The table below provides data on the extent to which such policies have been adopted, are in preparation, or are being considered.

	1993 Kushiro COP5	1996 Brisbane COP6	1999 San José COP7	2002 Valencia COP8	2005 Kampala COP9	2008 Changwon COP10	2012 Bucharest COP11

(d) No action yet reported	71%	71%	61%	41%	23%	23%	23%
Number of national reports tabled	**51 of 76**	**92 of 92**	**107 of 114**	**120 of 133**	**88 of 146**	**139 of 158**	**142 of 159**

Status of National Wetland Policies (Adapted from Ramsar Secretariat 2010 and updated from 2012 Ramsar Convention National Reports)

While there has been an increase in the adoption of national wetland policies, still only about half of Ramsar Contracting Parties report that they have done so. It is also important to note that wetland losses continue even when a national wetland policy is in place (Durigon et al. 2011).

97 National Wetland Policies: Overview

Marcela Bonells

Contents

Abstract

The Ramsar Convention on Wetlands, formally known as the "Convention on Wetlands of International Importance especially as Waterfowl Habitat," is an intergovernmental treaty for the "wiseuse" and conservation of wetlands, signed in Ramsar, Iran in 1971. It encourages its Contracting Parties to adopt National Wetland Policies as tools to achieve the wise use of wetlands and to implement the Convention at the national level. The force of law, content, scope and format of National Wetland Policies will vary from country to country depending on their government, legal systems and national context. This entry provides an overview about National Wetland Policies under the framework of the Ramsar Convention, highlighting the benefits and obstacles associated with adopting such policies, as well as the trends in their development and adoption by Ramsar Contracting Parties and future challenges for their development.

National Wetland Policies · Ramsar Convention on Wetlands · Wetland Conservation · Wise Use of Wetlands

Introduction

At the heart of the Ramsar Convention, an intergovernmental treaty for the "wise use" and conservation of wetlands, signed in Ramsar, Iran in 1971, is the concept of wise use (Ramsar Convention Secretariat 2008). The concept is implicit in the text of the Convention, which calls its Contracting Parties (or signatory member States) to conduct their planning in a way that promotes the conservation of wetlands in the List of Wetlands of International Importance (or Ramsar Sites List) and, "as far as possible the wise use of" all national wetlands (Ramsar Convention on Wetlands 2013a; Ramsar Convention Secretariat 2010). Wise use is defined as "the maintenance of [wetlands] ecological character, achieved through the implementation of ecosystem approaches, within the context of sustainable development" (Ramsar Convention on Wetlands 2005; Ramsar Convention Secretariat 2010).

To help implement the wise use of concept, the Convention recommends to its Contracting Parties to develop National Wetland Policies, among other tools (idem). While the precise definition of the term "policy" and its force of law may vary within each Contracting Party, National Wetland Policies are, in a broad sense, instruments that guide the integrated management and wise use of wetlands at the national level (Ramsar Convention on Wetlands 2013b). The structure and scope of National Wetland Policies may vary according to the government and legal systems of each Contracting Party, as well as their needs. However, the overarching goal of the policies, wetland protection and wise use, remains the same.

This entry first discusses the basis for National Wetland Policies under the Ramsar Convention, providing a definition of the term. Next, it explains the purpose and importance of such Policies, including the benefits and obstacles related to their adoption. Furthermore, the author discusses trends in the development and adoption of such policies by Ramsar Contracting Parties. Finally, this entry outlines future challenges related to the development of National Wetland Polices.

Background

Basis for National Wetland Policies Under the Ramsar Convention

National Wetland Policies are important instruments to help implement the Convention's wise use concept, implicit in Article 3.1 of the Convention's text (Ramsar Convention Secretariat 2010). To assist parties with the development of National Wetland Policies, the Convention has developed *Guidelines for developing and implementing National Wetland Policies*, through a series of Recommendations and Resolutions (*see* Recommendations: IV.10 (1990) and VI.9 (1996) and Resolutions: V.6 (1993) and VII. 6 (1999)) (idem). These decisions and recommendations have been compiled in volume two of the Ramsar handbooks for the wise use of wetlands series: *National Wetland Policies: Developing and implementing National Wetland Policies*.

Moreover, Strategy 1.3 of the Convention's Strategic Plan (2009–2015) calls Contracting Parties to develop by 2015, with the assistance of the Secretariat, National Wetland Policies, simultaneously with, and integrate them into, existing planning and strategic processes, such as water resources management strategies, coastal management plans and poverty eradication strategies, among others (Ramsar Convention Secretariat 2008). In this light, the Convention's National Reports, submitted by Contracting Parties before each Meeting of Conference of the Parties (COP), serve as a benchmark to assess progress towards the attainment of this objective, indicating whether Parties have in place a wetland policy or an equivalent instrument.

It is important to note that there is no single formula or process for developing, adopting, or updating National Wetland Policies. Instead, each country will develop, adopt, or update them according to their national contexts.

What are National Wetland Policies? Definition and Overview

National Wetland Policies are tools (usually in the form of documents) to ensure the wise use and integrated management of wetlands at the national level (Ramsar Convention Secretariat 2013; Ramsar Convention Secretariat 2010). Contracting Parties may have different definitions of the term "policy," and some may use the term interchangeably with "plan" or "strategy" (Ramsar Convention Secretariat 2010). For clarity and consistency, the Convention's handbook refers to "policy" in general terms as "a clearly published statement by a national or sub-national government, often with measurable goals, timelines and commitments plus budgets for action" (idem). In contrast, plans or strategies may, in some cases, provide a more general vision of a government's goals with specific deadlines and budget lines to be defined in the future (idem). It is worth nothing, however, that plans and strategies are equally important to policies, and there is no suggestion that a particular term is more suitable than the others (idem).

National Wetland Policies then will act as blueprints, expressing a government's vision, goals, objectives, actions, and commitments, as well as guiding decisions regarding wetlands and clarifying roles and responsibilities (Ramsar Convention Secretariat 2010). Policies may also provide an overview about the status of wetlands, as well as programs or strategies undertaken (idem). Policies are often broad in scope covering key policy areas and issues affecting wetlands in different sectors and jurisdictions and should seek to involve a broad spectrum of stakeholders (idem).

The scope, level of government, process, and legal instruments for developing and adopting National Wetland Policies vary from country to country. For instance, in countries with nonfederal governments, such as Colombia and Uganda, National Wetland Policies may be nation-wide in scope, while in countries with federal government systems, such as the United States and Canada, such policies may operate only at the federal level with additional policies developed at the subnational level (Ramsar Convention on Wetlands 2012). In some countries, National Wetland Policies may be standalone documents, while in others, such as the United States, the United Kingdom and New Zealand, they may be a collection of statements, documents, and programs (idem).

Similarly, in some countries, such as Pakistan, Thailand, and Japan, a cabinet may adopt Policies or equivalent instruments, while in others, such as Chile and Belarus, ministers may adopt them (idem; Ramsar Convention Secretariat 2010). Additionally, some countries may adopt policies or equivalent instruments formally through decrees or regulations, such as Guatemala and India, while others, such as the United Kingdom, may do so through statements or white papers (Ramsar Convention on Wetlands 2012). Likewise, depending on the legal and government systems of a country, a National Wetland Policy may be legally binding (or have the same weight as other laws, decrees or regulations), while in others it may be a guiding document to government agencies or ministries (Ramsar Convention on Wetlands 2012; Ramsar Convention Secretariat 2010).

In some countries, National Wetland Policies are standalone documents specifically dealing with wetland management and conservation, while in others, such as Bangladesh, Brazil, Denmark, Egypt, El Salvador, Italy, Japan, Lesotho, and Mongolia, among others, policies may be contained in other national or regional strategies; laws or policies, such as National Biodiversity Strategies and Action Plans, under the Convention of Biological Diversity; the European Union's Water Framework Directive; or the *Central American Policy on the Conservation and Wise Use of Wetlands*, under the Central American Commission for Environment and Development of the Central American Integration System (Ramsar Convention on Wetlands 2012).

It is worth mentioning that while many Contracting Parties have adopted National Wetland Policies after acceding to the Convention (or becoming Parties), some countries, such as Thailand, adopted standalone wetland policies before joining the Convention (Ramsar Convention on Wetlands 2012; Ramsar Convention Secretariat 2010). Therefore, although the means for adopting National Wetland Policies varies, as well as their scope and form, they all have the common goal of ensuring the wise use and conservation of wetlands, which in turns helps deliver the Convention at the national level.

Need for National Wetland Policies: Benefits and Obstacles

Wetlands play vital ecological functions in the water and chemical cycles (Russi et al. 2013; Barbier et al. 1997). They provide a wealth of ecosystem services to society, including regulating services (e.g., water quality and flow regulation, coastal erosion protection, flood control), provisioning services (e.g., food, medicines, genetic and natural resources, fresh water), supporting services ("those necessary for the production of all other ecosystem services"), and cultural services (e.g., bird watching, eco-tourism, cultural heritage) (Russi et al. 2013; Millennium Ecosystem Assessment (MA) 2005). However, despite being "amongst the most productive ecosystems on earth," wetlands have and continue to be progressively degraded and destroyed for land conversion, urban development and agriculture, among other activities (Barbier et al. 1997; MA 2005; Russi et al. 2013).

Adopting a standalone National Wetland Policy can be a tool to help stem the loss and degradation of wetlands by, for example, helping raise awareness about the value and functions of wetlands, which require different management approaches (Ramsar Convention Secretariat 2010). Since wetland issues are often confined to a single government agency or ministry and seldom covered in other policies or strategies, such as water resources management or agriculture, an individual policy can help mainstream wetland issues into other sectors and develop targeted actions to deal with such issues (idem).

Additionally, National Wetland Policies may be adopted to fulfill obligations under the Ramsar Convention and foster its implementation at the national level. They may also be adopted in response to national legislation or to address wetland issues, before a country becomes a Contracting Party to the Convention (Ramsar Convention on Wetlands 2012).

Therefore, given the vital services that wetlands provide and their continued loss, National Wetland Policies can be a key instrument for their wise use and conservation.

Benefits and Obstacles

Development of a National Wetland Policy can offer multiple benefits to Contracting Parties and countries that are not yet Parties to the Convention, including:

- Setting accountability mechanisms for government agencies and ministries' actions regarding wetland management and conservation
- Enhancing coordination and communication between government agencies and ministries that have jurisdiction over wetlands or whose actions impact wetlands
- Fostering partnerships with other sectors and actors that depend on wetlands or whose actions affect wetlands
- Mainstreaming wetland issues into other sectors and involving a wide range of stakeholders
- Promoting implementation of new and improved incentives (economic and non-economic) and discouraging perverse incentives and disincentives that contribute to wetland loss and degradation
- Raising awareness about the economic benefits that landowners and wetland managers can derive from the wise use of wetlands and how these benefits can contribute to the long-term management of wetlands

- Establishing Communication, Education, Participation and Awareness programs to engage local communities and stakeholders in wetlands management and decision-making
- Helping set the priorities and tools to improve awareness of wetland resources
- Establishing information priorities and strategies to obtain the information necessary for effective wetland management (Ramsar Convention on Wetlands 2012; Ramsar Convention Secretariat 2010)

Notwithstanding the benefits that establishing National Wetland Policies can provide, there are obstacles to their adoption and implementation, which include (Ramsar Convention Secretariat 2010; Ramsar Convention on Wetlands 2012; Ramsar Convention Secretariat 2012a, b, c, d, e, f):

- Lack of financial and human resources to develop, adopt, and implement a wetland policy
- Lack of communication and coordination between government agencies and ministries with jurisdiction over wetlands or whose actions affect wetlands
- Lack of inclusion of wetland issues into other sectoral policies or strategies and lack of intersectoral cooperation
- Limited knowledge and understanding of wetland issues among policy and decision-makers
- Absence of a legal framework and a clear mandate regarding an agency's responsibility towards wetlands
- Perverse incentives or subsidies contributing to wetland loss and degradation
- Slow administrative processes to adopt effective policies
- Lack of political interest to address wetland issues

Drafting and Organizing National Wetland Policies

While there is no single process for drafting and adopting National Wetland Policies, the Convention's guidelines outline several steps and priorities that should be considered by Parties seeking to develop a policy, including:

- Understanding and prioritizing the issues that need to be addressed by the policy
- Identifying and designating a lead government agency for the drafting process
- Understanding the requirements, issues, and resources needed for passage of the policy
- Ensuring there are sufficient financial and human resources for the drafting process
- Considering time-tables, since the drafting process may involve considerable time
- Identifying other sectors and stakeholders that should be involved in the drafting process
- Determining how and who will write the policy
- Drafting a national issues statement and background paper

- Establishing a cross-sectoral National Ramsar Committee (or equivalent body) to advice and assist with the drafting process (or involving it in the process where it exists)
- Conducting national consultations for the development of the policy
- Conducting National and local wetland workshops (Ramsar Convention Secretariat 2010).

Additionally, although the contents and structure of National Wetland Policies may vary from country to country, they commonly provide a historical overview about actions taken, as well as a foreword for the policy and an overview of a country's wetland status. Policies may also indicate the roles and jurisdiction of government agencies or ministries and outline cross-sectoral and interagency (interministerial) cooperation. Finally, policies frequently define the overarching goal of the policy, guiding principles, general and specific objectives, policy implementation strategies, and actions (idem).

Equally important to developing a National Wetland Policy is ensuring its implementation, through, for example, designating a responsible lead agency/ministry or organization, developing implementation guidelines, determining what resources will be needed, and ensuring they are (or will be) available, prioritizing objectives and setting timetables, as well as developing an implementation plan (idem).

Trends

Analyses of National Reports submitted by Contracting since the Third Meeting of the Conference of the Parties (COP3) (Regina 1987) show an increase in the number of Parties who have a National Wetland Policy, Action Plan, or Strategy (or equivalent instrument) in place (idem). Currently, the Convention has 169 Contracting Parties (Ramsar Convention 2016). An analysis of National Reports submitted to COP11 (147 reports), both before and after the submission deadline (Bucharest 2012), indicates that 50% of Contracting Parties (73) have in place a National Wetland Policy, Strategy, or Action Plan (or equivalent instrument) (Ramsar Convention Secretariat 2012a). Out of that percentage, three Parties indicated having a draft policy in place, pending approval (idem). Additionally, 11% of Parties (16) indicated planning the development of such a Policy, Strategy, or Action Plan, and 16% of Parties (24) stated being in the process of developing it (Ramsar Convention on Wetlands 2012). In contrast, 22% of Parties indicated not having such Policies, Strategies, or Action Plans in place (idem). Therefore, most Parties have a National Wetland Policy, Strategy, Action Plan, or equivalent instrument in place or are in the process of developing or planning one (see also Ramsar Convention Secretariat 2012b, c, d, e, f, g).

Future Challenges

National Wetland Policies are valuable tools to implement the Convention's wise use concept at the national level, helping raise awareness about wetland values, as well as coordination and management of wetland resources. While many Contracting Parties have adopted, or are in the process of adopting wetland policies, a number of challenges remain preventing effective implementation of such policies or their adoption by Parties who have not yet done so. Some of these challenges include: lack of resources (human and financial), political or administrative constraints, lack of cross-sectoral and inter-governmental cooperation, and lack of a legal framework.

National Wetland Policy: Australia

98

C. Max Finlayson

Contents

Abstract

In response to the requirements of the Ramsar Convention on Wetlands to ensure the wise use of wetlands, the Australian government developed a framework policy for the cooperative management of wetlands. This comprised a federal policy and an expectation that the state/territory jurisdictions would develop their own policies. The principal aim of the policy is to ensure that the Government's actions were consistent with those expected under the Convention, in particular the promotion of the wise use principles for wetland management. The policy was developed with and benefitted from consultation with wetland experts and key stakeholders and other government agencies.

Introduction

In response to the requirements of the Ramsar Convention on Wetlands to ensure the wise use of wetlands, the Australian government developed a framework policy for the cooperative management of wetlands (Environment Australia 1997). This comprised a federal policy and an expectation that the state/territory jurisdictions would develop their own policies. The principal aim of the policy is to ensure that the Government's actions were consistent with those expected under the Convention, in particular the promotion of the wise use principles for wetland management. The policy was developed within the framework of the National Strategy for Ecologically Sustainable Development and benefitted from consultation with wetland experts and key stakeholders and other government agencies. It also benefitted from advice based on the Canadian federal policy for wetland conservation (Government of Canada 1991).

Federal Policy

The Australian federal policy contained a goal, objectives, and a number of guiding principles. As stated in the policy document, "*The Goal of the Wetland Policy of the Commonwealth Government of Australia is to conserve, repair and manage wetlands wisely.*" Specific objectives include to:

- "*Conserve Australia's wetlands particularly through the promotion of their ecological, cultural, economic and social values*
- *Manage wetlands in an ecologically sustainable way and within a framework of integrated catchment management*
- *Achieve informed community and private sector participation in the management of wetlands through appropriate mechanisms*
- *Raise community and visitor awareness of the values, benefits and range of types of wetlands*
- *Develop a shared vision between all spheres of Government and promote the application of best practice in relation to wetland management and conservation*
- *Ensure a sound scientific and technological basis for the conservation, repair and ecologically sustainable development of wetlands*
- *Meet Australia's commitments, as a signatory to relevant international treaties, in relation to management of wetlands."*

Collectively, these provided specific direction for Government actions that directly or indirectly affected wetlands. The objectives and principles recognized the national importance of wetlands and supported a consistent approach for wetland management by all federal government organizations with responsibilities for wetlands. It was not backed by legislation and did not directly apply to the actions of the states/territories.

The policy included strategies, with priority actions, covering the following six major areas:

1. Managing wetlands on federal lands and waters
2. Implementing federal government policies and legislation and delivering federal programs
3. Involving the Australian people in wetlands management
4. Working in partnership with state/territory and local governments
5. Ensuring a sound scientific basis for policy and management
6. International actions.

The policy was supported by a number of principles including:

- The precautionary principle
- Coordination and cooperation across government and with the community, including indigenous people
- Empowerment of local landholders as custodians of wetlands
- The wise use of wetlands
- Integrated natural resource and land-use management
- The repair of degraded wetlands
- Ongoing research

An implementation plan was later provided (Commonwealth of Australia 1997).

The policy was not supported by specific legislation, although the Environment Protection and Biodiversity Conservation Act 1999 provided a legal framework for supporting the implementation of the Ramsar Convention, including the adoption of the key principles of wise use and maintaining the ecological character of all wetlands. This Act has been used to support the reporting of adverse change in the ecological character of two Ramsar sites:

- The Macquarie Marshes
- The Coorong and Lake Albert and Lake Alexandrina.

Further legislative support for the Convention has been provided through the Water Act 2007. Pittock et al. (2010) provided an overview of the manner in which Australia has responded to its obligation to make wise use and maintain the ecological character of all wetlands.

The federal wetland policy is currently under review with a National Wetlands Policy Statement being developed. It is expected that a draft of the Statement will be circulated for public/stakeholder comment, although the timeline for doing this is not known.

State/Territory Policies

In response to the federal policy being agreed, the states/territories were expected to also produce wetland policies and provide a complete national coverage of wetlands. This recognized that the state/territory jurisdictions had more direct management responsibility for wetlands than the federal government. Policies were subsequently produced in some of the state/territory jurisdictions.

- New South Wales: The Wetlands Policy promotes the sustainable conservation, management, and wise use of wetlands across the state and the need for all stakeholders to work together to protect wetland ecosystems and their catchments (State of NSW and Department of Environment, Climate Change and Water NSW 2010). It is accessible from http://www.environment.nsw.gov.au/resources/water/10039wetlandspolicy.pdf (accessed 30 August 2016).
- Western Australia: The Wetland Conservation Policy commits the government to identifying, maintaining, and managing the State's wetland resource, including the full range of wetland values, for the long-term benefit of the people of Western Australia (Government of Western Australia 1997). It is accessible from https://www.dpaw.wa.gov.au/images/documents/about/policy/wetlandspolicy_text.pdf (accessed 30 August 2016).
- Queensland: The Strategy for the Conservation and Management of Wetlands (The State of Queensland, Environmental Protection Agency 1999) aims to have wetlands, many of which are of international importance, managed in accordance with the goal, core objectives, and guiding principles set out in the National Strategy for Ecologically Sustainable Development (Commonwealth of Australia 1992), which incorporates economic, social, and environmental considerations. It is accessible from http://wetlandinfo.ehp.qld.gov.au/resources/static/pdf/resources/reports/wetland-strategy.pdf (accessed 30 August 2016).
- South Australia: The Wetlands Strategy for South Australia provides a framework for the sustainable use of wetland ecosystems with the goal to see wetlands recognized and managed as ecological and community assets for the benefit of present and future generations (Minister for Environment and Conservation 2003). It is accessible from http://www.environment.sa.gov.au/managing-natural-resources/wetlands (accessed 30 August 2016).
- Northern Territory: A Strategy Wetlands had the goal of conserving the biodiversity of the wetlands of the Northern Territory (Parks and Wildlife Commission of the Northern Territory 2000).

The legislative base for these policies is largely dependent on environment or conservation acts rather than specific legislation for the policies themselves. The federal environment act can be invoked if issues of national environmental significance arise, including actions that may affect Ramsar-listed wetlands. The outcomes of such interactions can be contentious, as is the effectiveness of the Water Act for supporting the maintenance of the ecological character of wetlands (see Pittock et al. 2010).

Mark Everard

Contents

Abstract

Canada hosts a major portion of the world's wetland resource base, encompassing more than 127 million ha of wetlands which represents up to one-quarter of the world's wetland area. *The Federal Policy on Wetland Conservation* was issued by the Government of Canada in 1991 following the development throughout 1986 and early 1987 of a national statement and fact sheet by the environmental regulator, Environment Canada. At the time of writing, Canada is considering revision of its Federal Wetland Policy.

Introduction

Canada hosts a major portion of the world's wetland resource base, encompassing more than 127 million ha of wetlands which represents up to one-quarter of the world's wetland area. *The Federal Policy on Wetland Conservation* was issued by the Government of Canada (1991), following the development throughout 1986 and early 1987 of a national statement and fact sheet by the environmental regulator, Environment Canada. The contents of this chapter derive substantially from descriptions in *The Federal Policy on Wetland Conservation* (Government of Canada 1991). However, Canada is considering revision of its Federal Wetland Policy at the time of writing.

Evolution of the Federal Policy

The statement and fact sheet developed by Environment Canada summarized management problems in Canada, identifying major obstacles to wetland conservation. From these sources, a Canadian Government-sponsored workshop to develop a *Wetland Conservation Policy* produced a series of recommendations relating to the need for wetland policy. Environment and Natural Resource Ministers from Provinces across Canada received copy of these outputs.

Consequently, the Federal-Provincial Committee on Land Use (FPCLU) in 1987 identified "wetlands management" as a significant land use issue. A Wetlands Subcommittee of the FPCLU reported on a framework for a Wetlands Policy predicated on the FPCLU's own "wise land use" provisions. This policy development activity was also spurred by Canada having been a signatory nation to the Ramsar Convention for some years, hosting the Third Conference of the Contracting Parties at Regina in 1987, and hence bearing an obligation to implement the principles of the Convention.

The Federal Government's intention to act on wetland policy in 1990 formed part of the national Green Plan. Following a series of consultations throughout the summer of 1990, identifying widespread public support for the conservation of Canadian wetlands, *The Federal Policy on Wetland Conservation* was formally adopted in 1991.

Canada's *Federal Policy on Wetland Conservation*

The Federal Policy on Wetland Conservation recognizes wetlands as important for a diversity of beneficial services – from water recharge, purification, and storage through to shoreline protection, flood regulation, habitat for rare species, and soil and water conservation, as a subset of examples – serving a range of socioeconomic functions cumulatively worth billions of dollars.

Notwithstanding recognition of the high importance of wetlands, the *Policy* also recognized the magnitude of wetland loss comprising an estimated 20 million ha (one seventh of Canada's total wetland base) drained or lost since 1800. This further justified the need for a Federal policy, sharing wetland conservation across federal, provincial, and territorial remits, including addressing transboundary resources such as water and wildlife. Policy review of the (then) over 900 Federal policies and programs across Canada was a priority, recognizing that many of these directly or indirectly affected wetlands.

The objective of the Federal Government with respect to wetland conservation is to, "*. . .promote the conservation of Canada's wetlands to sustain their ecological and socio-economic functions, now and in the future.*" Goals supporting these objectives include the Federal Government, in cooperation with the provinces and territories and the Canadian public, striving to achieve:

- *Maintenance* of the functions and values derived from wetlands throughout Canada
- *No net loss of wetland functions* on all federal lands and waters
- *Enhancement and rehabilitation* of wetlands in areas where the continuing loss or degradation of wetlands or their functions have reached critical levels
- *Recognition* of wetland functions in resource planning, management and economic decision-making with regard to all federal programs, policies, and activities
- *Securement* of wetlands of significance to Canadians
- *Recognition of sound, sustainable management practices* in sectors such as forestry and agriculture that make a positive contribution to wetland conservation while also achieving wise use of wetland resources
- *Utilization* of wetlands in a manner that enhances prospects for their sustained and productive use by future generations.

A range of guiding principles form part of the *Policy*. This addresses issues such as the contribution of wetlands and their functions to the health and wellbeing of Canadians, incorporating wetland conservation into the economic decision-making process, taking an integrated systems approach, using evolving science, taking a cooperative approach including with native institutions and representatives, as well as communication and education programs.

Strategies to Implement the *Policy*

The Federal Policy on Wetland Conservation also outlines seven strategies for the sustainable use and management of wetlands, spanning:

1. Developing public awareness
2. Managing wetlands on Federal lands and waters and in other Federal programs
3. Promoting wetland conservation in Federal Protected Areas

4. Enhancing cooperation
5. Conserving wetlands of significance to Canadians
6. Ensuring a sound scientific basis for policy
7. Promoting international actions

The definition of "Wetland" in the Policy varies somewhat from the Ramsar Definition, describing a wetland as, "*…land that is saturated with water long enough to promote wetland or aquatic processes as indicated by poorly drained soils, hydrophytic vegetation and various kinds of biological activity which are adapted to a wet environment.*" The *Policy* recognizes that wetlands include bogs, fens, marshes, swamps, and shallow waters (usually 2 m deep or less) as defined in *The Canadian Wetland Classification System* published by the National Wetlands Working Group of the Canada Committee on Ecological Land Classification (1987). [This Classification System has subsequently been superseded by the *The Canadian Wetland Classification System, Second Edition* (Warner and Rubec, 1997), classifying a complex range of natural and constructed wetland types also taking account of chemical and hydrological conditions.]

Wetland policy is then continuing to evolve with improvements in science.

State-level Action

Most of the action required under Federal policy occurs at Province level. Consequently, below the federal level, a range of Canadian Provinces have evolved their own bespoke wetland policies.

As one example, the Alberta Government (2013) released the *Alberta Wetland Policy* in 2013 in order to provide "*…the strategic direction and tools required to make informed management decisions in the long-term interest of Albertians.*" The *Alberta Wetland Policy* includes minimization of loss and degradation of wetlands "*…while allowing for continued growth and economic development of the Province.*" The *Alberta Wetland Policy* is focused on four outcomes: (1) protecting wetlands of the highest value; (2) conserving and restoring wetlands and their benefits; (3) avoiding, minimizing, or replacing lost wetland value; and (4) considering regional context.

Conclusions

The Federal Policy on Wetland Conservation in Canada, formally adopted in 1991, has continued to evolve on the basis of its founding principles, objectives and guidance, informed by an improving science base. Management of wetlands entails linking scales from the Federal to the Provincial and the local, also taking account of transboundary issues. As most action occurs at the Provincial level, some Provinces have adopted their own, regionally tailored wetland policies.

At the time of writing, Canada's Federal Wetland Policy is under revision.

National Wetland Policy: Chile

100

Adriana Suárez-Delucchi

Contents

Abstract

Since the 1990s, Chile has experienced an accelerated pace of economic development that has been mainly based on the exploitation of its natural resources. The dependence on raw materials and an accelerated economic growth has increased the threats imposed to biodiversity, ecosystems and the livelihoods of indigenous and local communities that live upon them. This chapter outlines the geographic distribution of wetlands in Chile and the national and regional efforts to protect and manage these ecosystems. Important challenges remain in order to achieve effective wetland conservation, especially in terms of enabling an effective participation of local communities in natural resources management.

Introduction

Since the 1990s, Chile has experienced an accelerated pace of economic development that has mainly been based on the exploitation of its natural resources. Mining activities accounts for 46% of national exports, while agriculture, fisheries, and forestry contribute to 40% (OECD and CEPAL 2005). Chile's dependence on raw materials has increased threats to biodiversity and ecosystems.

However, the return of democracy and democratic institutions in 1990 encouraged the promotion of environmental protection and strengthened Chile's international commitment to work towards sustainable development. In 1971, the Chilean Government became a signatory of the Ramsar Convention, which came into force in 1981.

Although Chile is not rich in terms of overall quantity of species when compared to tropical areas, it is nevertheless important in terms of the genetic variability existing between species and for the presence of an important number of endemic species, which represent a genetic patrimony unique in the world. For example, 85.5% of Chilean flora has its origin in Chile, from which 44.6% are endemic (Manzur and Lasen 2003).

Wetlands in Chile

A survey undertaken in 1999 concluded that Chile encompassed 4.5 million hectares of wetlands, representing 6% of the national territory. These wetlands are highly diverse in nature, largely due to the wide diversity of bioclimates found across the country.

Geographical Distribution of Wetlands in Chile

From the north of the country to as far south as Santiago, drainage basins tend to be arid or semiarid; consequently, wetlands are scarce in this part of the country, occurring only in exceptional situations. The term *bofedal* (wetlands located at more than 2800 m in the High Andes) is mainly used by the *Aymará* people in the Parinacota province, whereas the name *vega* is used by the Atacameños to identify the vegetation associated with wetlands. These indigenous cultures are closely linked to wetlands and have vernacular names for a high percentage of wetland species. They consume wetland resources such as fish and algae, divert water resources and use these areas for grazing (Centro de Ecología Aplicada and CONAMA 2006).

Coastal wetlands occur in the central region of Chile, located on bays and estuaries with both oceanic and continental water influences. These coastal wetlands are rich in biodiversity. Of a total of 63 species of flora located in the area of Coquimbo, 17 are considered native, 19 are endemic, and 5 have been classified as vulnerable. In terms of fauna, out of a total of 173 species, 15 are considered endemic to Chile, 8 are native, 4 are in danger of extinction, 11 are vulnerable, and 1 is considered rare (Centro de Ecología Aplicada and CONAMA 2006).

Towards the south of the country, wetlands are more frequent and they have also concentrated the activities of different cultural groups for centuries. *Hualves*, boggy wetlands dominated by arboreal species, are found in the Araucanía region. *Ñadis* (meaning 'seasonal swamps' in Mapudungun: the Mapuche language) are also present in the Araucanía and in the Lakes region. Flat areas with volcanic soil are also found here, constituting a waterproof horizon which is drenched for a period of 4–8 months a year. Further south, there are *turbas* (peatlands) and *mallines*. The latter are sunken, water-saturated areas with alluvial and aeolic sediments, with characteristics of gleysolic soils (Centro de Ecología Aplicada and CONAMA 2006).

Chilean Wetlands of International Importance

Chile has declared 12 Ramsar sites of international importance. These are located in the High Andes (7), the coast of central Chile (2), the mountainous area of central Chile (1), and at the coasts of the Lakes Region (1) and the Magallanes Region (1). In total, these Ramsar sites represent 205,876 ha. Ten of these sites are managed by public institutions, and two are under private management (CONAF 2010).

Chile participates in a range of regional initiatives to protect migratory species that depend on wetlands, including for example two Memoranda of Understanding (MoUs) signed with Argentina; one of them aims at protecting the *canquén de cabeza colorada* (the ruddy-headed goose, *Chloephaga rubidiceps*) and the other protects the *huemul* (the south Andean deer, *Hippocamelus bisulcus*). Another MoU has been signed with Perú and Bolivia for the conservation of flamingos. The AGCI (Chilean Agency for International Cooperation) project between Chile and Mexico promotes the standardisation of strategies and protocols on awareness-raising about the importance of wetlands in both countries (Informe Nacional Ramsar 2014).

Chile's National Wetlands Strategy

A document outlining Chile's National Wetlands Strategy (NWS) was developed in 2005. The Strategy has enabled the country to work towards a coordinated and efficient protection of priority wetlands in Chile, and to highlight their importance for sustainable development. The NWS complements the priorities promoted by the Chile's National Biodiversity Strategy (CONAMA 2003), which itself serves the vital function of representing a wider framework for conservation in the country. The NWS states that *wetlands are zones where biodiversity concentrates, and they determine the functioning of ecosystems and hence, of human life* (CONAMA 2005).

One of the objectives of the NWS is to *increase knowledge about wetlands*. In order to achieve this objective, Chile's Ministry for the Environment has created a system to classify Chilean wetlands in relation to their functions and structural characteristics, as a transparent basis for defining different ecotypes of wetlands. Each ecotype is associated with particular functions and threats, enabling development of generic management plans for each ecotype (MMA and Centro de Ecología Aplicada 2011).

A National Wetlands Inventory capturing this information is currently being developed. A wetland information system will become available to the general public, containing complete information on the wetlands that have already been surveyed. The General Water Commission (DGA, associated with the Ministry of Infrastructure) manages and shares information related to water quality and seasonal flow rates of the main rivers and lakes the Commission monitors (Informe Nacional Ramsar 2014).

Another objective of the National Wetland Strategy is to raise environmental, economic, social, and cultural awareness about wetlands. The NWS document also refers to the importance of implementing a legal and institutional framework for the conservation and sustainable use of wetlands. The participation of different actors – such as the private sector, indigenous peoples, universities, and NGOs – is specifically referenced, and the need to develop tools for participatory planning and management of priority wetlands is also stressed (CONAMA 2005).

National Wetlands Action Plan

In order to implement the NWS, a National Wetlands Action Plan was created in 2006. Different governmental organisations participated in its creation including the DGA, the Agriculture and Livestock Service (SAG), the National Natural History Museum (MNHN), the National Forestry Corporation (CONAF), and the National Commission for the Environment (CONAMA) which has been replaced by the Ministry for the Environment (MMA). The National Wetlands Action Plan is currently under review.

National Wetlands Committee

A National Wetlands Committee was also formed in 2005, directed and coordinated by the Ministry for the Environment. The Committee is formed by the Ministry of Foreign Affairs, the DGA, National Commission on Irrigation, SAG, CONAF, MNHN, SERNAPESCA (the National Fishery Service), SERNAGEOMIN (National Geological and Mining Service), and DIRECTEMAR (the Commission for Maritime Affairs).

The Committee meets monthly, and also for special activities if required by any of its members. Committee members analyze documents from the COPs of the Ramsar Convention, so that they can agree on a national view on a range of matters including, for example, the listing of new Ramsar sites and implementation of the NWS and its Action Plan.

Regional Conservation and Sustainable Use Under the High Andean Wetlands Strategy

The Ramsar Convention recognizes the importance of High Andean wetlands as strategic ecosystems, promoting international cooperation in order to preserve their valuable biodiversity, their role as water regulators and as vital spaces for a range of local communities in the Andes, including farmers and indigenous peoples (CONAF 2010).

Argentina, Bolivia, Chile, Perú, Ecuador, Venezuela, Colombia, and Costa Rica, with the support of the IOPs (International Organization Partners), the Flamingo Conservation Group, CREHO (Ramsar Regional Centre for the Western Hemisphere), and CONDESAN (Consortium for Sustainable Development of the Andean Ecoregion), developed in 2005 the High Andean Wetlands Strategy.

Challenges

- There is still much to do in terms of implementing effective planning, including Strategic Environmental Assessments, in those places where policies, programs, plans and development projects could impacts on wetlands and on the local and/or indigenous communities surrounding them.
- Limited funds are inhibiting effective wetland conservation, allied with a lack of applied and basic research on wetland ecosystems.
- There is a need for specific planning for each Ramsar Site and a higher level of commitment from the private sector.
- Monitoring and surveillance are especially important. It has been necessary to implement new environmental institutions, especially in the areas of biodiversity conservation and monitoring, for example with the replacement of CONAMA with the new Ministry for the Environment (MMA) (Informe Nacional Ramsar 2014).
- Governmental institutions are currently working on the national inventory on wetlands, which will support implementation of the Ramsar Convention and the National Wetland Strategy. This is considered a fundamental step towards achieving the sustainable management of Chile's wetlands (CONAMA 2005).
- There is a need for greater community participation in the management of wetland resources, through deliberate efforts for cooperation between public authorities and local communities in ways that promote sustainable and just outcomes.

Background

The diverse types of wetlands found in China range from those found in cold temperate to the wetlands of tropical zones, from plains to mountainous regions or plateaus, and from coastal to inland areas. The second wetland resource census of China indicates that the total area of Chinese wetlands is 53.6 million ha (excluding 30.06 million ha of paddy fields which are additional to this area), accounting for 5.58% of the national territorial area. Within this total area of wetland, the area of offshore and coastal wetland is 5.80 million ha, the area of river wetland is 10.55 million ha, the area of lake wetland is 21.73 million area, and the area of constructed wetlands is 6.75 million ha. There are 4220 types of wetland plants that belong to 438 biomes, and 2312 types of vertebrates that include 231 types of wetland birds.

Significant change has occurred throughout history in Chinese wetland conservation and management policy. In the 1950s, due to the lack of food production, the Chinese government introduced a food production-oriented policy which led a large amount of wetland conversion into farmland. A typical example is the Sanjiang plain wetland, the total area of which reduced by 60%. The Sanjiang plain wetland is now the most important grain production base in China. In the east-south region of China, the large-scale activity of reclaiming farmland from lakes resulted in rapid shrinkage of wetland extent while, in the coastal region of China, large amounts of mud flats have been converted into salt ponds, aquaculture ponds, and farmland. However, since 1992 when China joined the Ramsar Convention on Wetlands, the Chinese government has started to pay increasing attention to wetland conservation and has established strategic targets and supporting administrative departments and support mechanism, introduced a large number of action plans, planning processes, rules, regulations and laws, and operated national-level wetland conservation and restoration projects. By January 2014, China had 577 wetland nature reserves and 468 wetland parks, among which 46 had been listed as Ramsar wetlands of international importance.

The Strategic Targets of Chinese Wetland Conservation

Under its general targets of wetland conservation and wise use, the Chinese government gives priority to wetland conservation. In wetland conservation, priority is given to the conservation of natural wetland ecosystems (prevention first), supplemented by demonstration-scale ecological restoration and reconstruction of degraded wetlands, as well as the establishment of demonstration zones of wetland wise use.

As a matter of public interest, the Chinese government promotes policies to reduce the further degradation and loss of natural wetlands. The number of wetlands is expressly stated in the national ecological conservation system. The Chinese government has also strengthened supervision on the utilization of natural wetlands based on the principles of sustainable management of ecological systems and the practice of catchment management. Another important target is the operation of national key wetland protection projects (NWKCPs). Additionally, the Chinese government advocates the importance of public awareness of wetland conservation and the need for greater respect for the values and benefits provided by wetlands, in order to achieve the coadministration of wetland resource between the community and wetland managers. Key stakeholders in this coadministration include government departments, social organizations, private institutions, and international organizations.

In order to achieve the strategic targets of national wetland conservation, the NWKCPs place differential emphasis on different levels of governance: (1) at regional level, NWKCPs particularly support the coadministration aspects of community wetland conservation and wetland resource, including wetland restoration through changing local people's intensity of resource utilization; (2) at national level, NWKCPs particularly support wetland co-administration including the involvement of the provincial government level, including improvement of the capacity of provincial wetland conservation agencies and the establishment of regional integrated conservation mechanisms; and (3) at global level, NWKCPs particularly support the Ramsar Convention on Wetlands and the associated conservation needs of migratory water birds.

The broad objectives of the wetland conservation policy environment are to form a natural wetland conservation system through the protection of biodiversity, control of pollution, and adjustment of land use types, in order to maintain the natural characteristics and essential functions of wetland ecosystems, reversing the historic trend of shrinking wetland area and degrading wetland function. Implementing restoration and improved management of degraded wetlands in key ecological regions is a priority, serving systematically to restore natural wetlands and their ecological functions. So too is putting in place processes for assessing and consenting wise use of natural wetlands, with associated regimes appropriate for wetland monitoring and ecological risk assessment. It is also necessary to strengthen surveillance monitoring of the wetland resource and to improve capacity building for wetland advocacy, education, research, and technology promotion. This also necessitates the establishment of a robust wetland conservation management system, legal system, and research system. The ultimate objective is to improve the level of wetland conservation, management, and wise use in China; to form a complete natural wetland conservation network such that 90% of wetlands can be maintained in good status; to achieve the "virtuous circle" of wetland conservation and wise use; and to maintain and develop the various functions and benefits provided by wetland ecosystems, so enhancing their contribution to sustainable economic and social development.

The Management Agencies and System of Wetland Conservation

In order to fulfill the clause of the Ramsar Convention that "...all Parties have responsibilities and obligations to protect, manage and wisely use the wetland" since China joined the Ramsar Convention on Wetlands, the State Council has established a wetland management system in which State Forestry Bureaus take the lead. In this, they are assisted by related departments such as the Water Conservancy Bureau, Agricultural Departments, the Land Resource Management Bureau, Environmental Protection Departments, the Development and Reform Commission, the Oceanic Administration, and the Shipping Department. The State Forestry Bureau Wetland Conservation Management Centre (The Ramsar Convention Compliance Office of the People's Republic of China) was established in 2005. Subsequently, Forestry Departments in each province founded provincial management offices or centers for wetland conservation, and a proportion of counties (cities), wetland nature reserves, and wetland parks have also founded special wetland management agencies. In 2007, the State Council approved the National Ramsar Convention Compliance Council that was composed by 16 departments.

Currently, a wetland management system that incorporates wetland nature reserves, wetland parks, wetland protection areas, and multifunction zones has taken shape in China.

- A "wetland nature reserve" is an area delimited for special protection and management of the land, water, or ocean as it is representative of a particular natural ecological system; contains a significant concentration of rare and/or endangered wildlife species; or contains some other special natural feature designated under the law. Thus, a wetland nature reserve is the highest level of designation within the wetland management system.
- A "wetland protection area" is a region designated as a means to strengthen wetland resource protection. This is to ensure the health of the wetland ecosystem, to achieve comprehensive benefits for the wetland, and to contribute to overall regional ecosystem structure. Compared with a wetland nature reserve, a wetland protection area is a lower-level management unit, emphasizing its importance to local ecosystem structure.

- A “Wetland Park” is an area of wetland landscape, or a wider landscape of which wetlands are important constituent units, the protection of which demonstrates ecosystem services and functions, serves as an advocacy or educational resource, demonstrates the wise use of wetlands, contains specific cultural and/or aesthetic value, and may also provide a place for scientific research and ecotourism.

Laws and regulations for Wetland Protection

Before China joined the Ramsar Convention on Wetlands, concepts such as “mud flat,” “river,” “lake,” “ditch,” and “reservoir” were scattered in laws, regulations, policies, and plans. After China joined the Ramsar Convention in 1992, the concept of “wetland” was referenced in “the People’s Republic of China Natural Reserve Regulation” in 1994. Subsequently, “wetland” generally appeared in 15 laws and regulations such as the “Marine Environment Protection Law,” the “Forestry Law,” the “Wild Animal Protection Law,” the “Environment Impact Assessment Law,” the “Administration of the Use of Sea Areas,” the “Water Law,” and the “Law on Prevention and Control of Water Pollution”.

Since 1998, the National Forestry Bureau started the legislative work for wetland protection, and provincial governments started their work in formulating regulations for wetland conservation. The publication of “Heilongjiang Province Wetland Conservation Regulation” provided provincial legal safeguard for wetland management for the first time (Li 2000). Up to 2004, a total of 19 provinces (municipalities) had issued and implemented provincial wetland conservation regulations, including Heilongjiang, Gansu, Hunan, Shaanxi, Guangdong, Inner Mongolia, Liaoning, Ningxia, Jilin, Jiangxi, Sichuan, Tibet, Xinjiang, Qinghai, Yunnan, Zhejiang, Shandong, Beijing, and Hebei. Regulations from city and county levels have also appeared progressively. However, despite this plethora of legislation, there is at present no nation law specifically focused on wetland conservation.

Plans and Related Policies of Wetland Conservation in China

Since joining the Ramsar Convention in 1992, China has put in place a wide range of legal instruments and policy directions to protect and restore its wetland resource. Examples include:

- In 1993, The State Council approved the “Action Plan of China Environmental Protection (1991–2000)”, which set the establishment of oceans, wetlands, grasslands, deserts, and natural heritage wetland as important targets, confirming the content of wetland conservation in national plan.

- In 1994, China included wetland conservation and wise use in “21st Century Agenda – China’s population, environment and development white paper in the 21st century” and “China Biodiversity Conservation Action Plan.”
- In 1995, the Ministry of Forestry implemented the first national wetland resource census.
- In 1996, the State Council identified “wetland conservation” as one of the essential areas of natural conservation in “The ‘ninth five-year plan’ and 2010 vision of state environmental protection.”
- In 2000, the National Forestry Bureau and another 17 governmental departments jointly released the “Chinese Wetland Protection Motion Plan.”
- In 2003, the National Forestry Bureau drew up the “The national wetland protection engineering planning (2002–2030)” and implemented the “Grain for Wetland Project.”
- In 2004, the State Council published “the notice of General office of the state council on strengthening the management of the wetland protection.”
- In 2005, the State Council approved “the national wetland conservation project implementation plan (2005–2010),”, investing 3.1 billion Yuan for recurring conservation on important wetlands.
- In 2009, the State Council launched the second national wetland resource census and implemented the pilot of “the wetland ecological benefit compensation.”
- In 2010, the State Council published “the implementation opinions on wetland conservation subsidies in 2010” with an emphasis on “wetland conservation well” in the “On the twelfth five-year plan for national economic and social development program.”
- Between 2010 and 2011, the National Forestry Bureau issued the “National wetland park management approach (trial),” “National wetland park planning guide,” and “National wetland park pilot acceptance method (trial)” successively.
- In 2012, the State Council approved the “Twelfth five-year national wetland conservation project implementation plan” drawn up by the National Forestry Bureau.
- In 2012, the No. 32 regulation published by National Forestry Bureau in the “Wetland protection regulations” confirmed the contents of wetland conservation, planning, monitoring, restoration and wetland park construction, assessment, and management.

Over the past twenty years, the historic trend of wetland shrinkage and degradation has been revered through the concerted efforts of all levels of government and their relevant departments. This has encompassed a wide range of wetland conservation measures, pollution control, and land use adjustment, as well as major restoration projects, including “Grain for lake” and “Grain for wetland,” that have contributed significantly to the conservation and restoration of formerly degraded wetlands.

Challenges of Wetland Conservation

Despite these significant achievements, wetland-specific laws are still absent at national level to support wetland conservation work in China. Aside from the "Nature reserve ordinance," the majority of laws and regulations do not yet emphasize the integrated conservation of wetlands and biodiversity, which creates some difficulties for wetland resource conservation.

The conservation and management of Chinese wetlands requires the involvement of multiple government departments. However, the diversity of wetlands and the complexity of their functions span jurisdictional boundaries and can create conflicts. Where responsibilities remain unidentified, this can seriously restrict the performance of wetland conservation agencies. Wetland conservation in China mostly depends on the strength of government, lacking effective participation pathways for local residents, communities, and non-government organizations (NGOs). This deficit in public participation acts contrary to the efficient resolution of conflicts between environmental and economic benefit.

The conservation and management of wetlands in China also faces a shortfall of financial support necessary for wetland resource investigation, establishment of conservation areas and demonstration areas, and to put in place pollution control, law enforcement, and effective management teams. In the majority of situations, government is the single source of finance, with no other options for diversifying investment. In response to the challenges of wetland conservation and management, China should in future take the following measures:

- Based on the principles of sustainable development, publish a specific law on wetlands that incorporates ecological protection, resource development, and pollution control according to nationally consistent conditions
- Confirm the jurisdiction of different departments and types of wetland ownership
- Complete the coverage of wetlands across the legal system, and manage wetlands according to this more integrated legal framework
- Achieve "one district one law" in some important wetlands

In order to integrate wetland ecosystem protection, it is necessary to:

- Strengthen coordination both within and between departments to enforce the overall protection and efficient use of wetlands
- Reform responsibilities to bring about improved coordination of wetland resource management, confirming the core duties of wetland management agencies as a means to protect the integrity of wetland ecosystems
- Establish mechanisms of "community co-management" and "public participation," build information-sharing platforms for wetlands, and encourage public participation in wetland conservation

- Establish and complete ecocompensation systems for wetlands. This includes integrating wetland conservation into the national economy and social development plan, enforcing financial investment in wetland conservation, building a financial safeguard system that guides and encourages investment by enterprises, the public and NGOs, and promoting the conservation and sustainable development of wetlands; and
- Launch technological innovation to strengthen scientific understanding of wetlands and to better inform wetland conservation and restoration.

National Wetland Policy: Ghana

102

Mark Everard

Contents

Abstract
Wetland ecosystems in Ghana constitute about 10% of the country's total land surface, comprising marine/coastal, inland, and man-made systems. To protect and drive the sustainable use of these resources, Ghana instituted a National Wetland Strategy in 1999. This encyclopedia entry is summarized from the full Strategy document.

Managing Ghana's Wetlands: A National Wetlands Conservation Strategy

Ghana's national wetland strategy, contained in the Ghanaian Government publication *Managing Ghana's Wetlands: A National Wetlands Conservation Strategy* (Republic of Ghana 1999a), recognizes that, until relatively recently before the strategy was developed, "…wetlands were virtually considered as "waste lands"

M. Everard (✉)
International Water Security Network, University of the West of England, Bristol, UK
e-mail: mark.everard@uwe.ac.uk; mark@pundamilia.co.uk

C. M. Finlayson et al. (eds.), *The Wetland Book*,
https://doi.org/10.1007/978-90-481-9659-3_158

or areas that only served for breeding mosquitoes." This had formerly led to widespread dredging and drainage, wetland conversion for other uses, or the use of wetlands as dumping grounds for refuse. Neither were there effective controls or constraints on harvesting of wetland resources such as fish, reeds, mangroves, and thatch materials. The net consequence was a diminishing wetland resource.

Particularly since the Ramsar Convention came into force in 1971, wetlands have been increasingly recognized by the international community as ecosystems of considerable importance, comparable to forests, rangelands, and marine ecosystems. The Government of Ghana, as a signatory of the Convention since 1988, recognized the high degree of importance of the nation's wetlands as habitat for wildlife; maintenance of water tables; flood management and water purification; for wider socioeconomic benefits such as providing materials for construction and crafts; and for supporting beneficial uses such as fishing, hunting, grazing, crop production, and domestic water supply.

Recognizing this broad range of values, Ghana's National Land Policy in June 1999 (Republic of Ghana 1999b) precluded a range of practices directly damaging the wetland resource including:

- Physical draining of wetland water
- Draining of streams and watercourses feeding the wetlands
- Human settlements and their related infrastructural developments in wetlands
- Disposal of solid waste and effluents in wetlands
- Mining in wetlands

This was backed up by a program of research and public awareness-raising promoting the values of wetlands and the importance of their conservation and sustainable use to sustain a range of human benefits. This led in turn to publication of *Managing Ghana's Wetlands: A National Wetlands Conservation Strategy*, to promote participation of local communities and other stakeholders in the sound management and sustainable utilization of Ghana's wetlands and their resources.

Ghana's National Wetland Strategy categorized many of the nation's natural coastal and inland wetlands, as well as constructed wetland systems, recognizing their breadth of associated functional, productive, natural, and cultural/heritage values to society.

The Strategy also classified and described threats to wetlands including: water loss, loss of run-off control, infilling or other forms of conversion, hydrological disconnection, saltwater intrusion and soil salinization, soil degradation, pollution, overexploitation, deforestation, sediment and nutrient diversion, and disruption of stable climatic conditions.

The Strategy also listed a number of Ghanaian policies relevant to wetland use and conservation. It recognized that traditional and indigenous management practices are of value in protecting wetlands, incorporating as they do customary laws, informal agreements such as abstaining from fishing in certain fish nursery areas, or taboos. Many of these measures determine rights to land and resource use.

The Government also restated its commitment to restoration and protection of wetlands, for ecological and livelihood benefits.

The stated nine guiding principles in the Strategy include:

i. ***Wise use***, with an emphasis on managing wetlands within biological and physical constraints, to ensure that future generations have access to the same resources as the present generation.
ii. ***Interdependence*** between physical, biological, social, cultural, economic, technological, and environmental conditions of wetland ecosystems.
iii. The ***precautionary principle***, by avoiding activities which would affect the integrity of wetlands and subjecting all development activities to an environmental impact assessment process.
iv. The "***polluter pays principle***," applied to all development activities in wetland habitats.
v. ***Local knowledge and traditional management strategies*** play a role in the management of wetlands.
vi. The livelihood of local communities within the catchment area is ***interlinked*** with the ecological integrity of wetlands.
vii. ***Taking a participatory approach*** through involvement of traditional authorities, local communities, and all concerned people and organizations at levels of decision-making in the sustainable management of wetlands.
viii. Provision of ***incentives and disincentives*** as effective means for managing the use of wetlands and wetland resources.
ix. ***International cooperation*** as an essential measure for the conservation and management of shared wetland resources.

The published Aim of the Strategy is ". . .ensuring the wise use of wetlands for the benefit of the country and its people, present and future." This Aim is backed up by five Objectives:

- To promote the participation of local communities, traditional authorities, and other stakeholders in sound management and sustainable utilization of Ghana's wetland resources.
- To maintain the ecological, cultural, recreational, and aesthetic values of wetlands.
- To ensure that national policies, local knowledge, regulations, and activities contribute to the wise use and sound management of Ghana's wetland resources.
- To ensure that national capacity-building and appropriate legal and institutional frameworks are put in place for effective wetland conservation.

- To create awareness among the people of Ghana on the importance of wetlands and solicit their commitment to conservation and wise use.

Strategies for implementation cover a range of time horizons – short-term (1–2 years), medium-term (3–5 years), and long-term (more than 5 years) – and also recognize a number of priority cross-sectoral issues associated with wetland management in Ghana.

Challenges

At the time of publication (1999), the *National Wetlands Conservation Strategy* recognized the transition from recent conception of wetlands as "...'waste lands' or areas that only served for breeding mosquitoes" through to an integrated strategy with valuation, conservation, and wise use of wetlands at its core. This was also connected with Ghana's national vision for 2020, recognizing the scale of transformation.

While progress has been made with wetland conservation and aspects of wise use, full realization of the goals of the Strategy clearly remain long-term aspirations with their associated challenges.

National Wetland Policy: New Zealand

103

Mark Everard

Contents

Abstract

In 1986, New Zealand became the first Contracting Party of the Ramsar Convention to publish a Wetland Management Policy. Interpretation and context have changed since publication of the New Zealand Wetland Management Policy, which the New Zealand Government is considering updating. The Policy recognizes that the wetlands of New Zealand have always been an important part of the nation's environment, from the earliest days when Maori settlers harvested shellfish and fin fish, collected material for weaving and farmed the extensive flat swamplands. Drainage of wetlands for economically productive farming has been a continuing trend, leaving few of New Zealand's native lowland wetlands intact and compromising their capacity to provide habitats for plants and other wildlife. The New Zealand Wetlands Management Policy recognizes the difficulty of reversing this trend towards drainage for short-term gain.

Introduction

In 1986, New Zealand became the first Contracting Party of the Ramsar Convention to publish a Wetland Management Policy. A scanned copy on the *New Zealand Wetlands Management Policy 1986,* can be found on the Ramsar Commission (n.d.) website. However, the New Zealand Department of Conservation has added a note stating that: "*As the first National Wetland Policy by a Contracting Party, this document is becoming outdated in terms of both the evolution of the Convention and the changes in legislation and governance structures in New Zealand during the past thirteen years. Accordingly, a stock-taking of implementation is currently under way, which may lead to a formal review of the policy*".

The contents of this chapter are derived from the wording of the *New Zealand Wetlands Management Policy*, though with the cautionary note that interpretation and context have changed since its publications and that the New Zealand Government is currently considering updating the Policy.

New Zealand's Wetlands

The *New Zealand Wetlands Management Policy* recognizes that the wetlands of New Zealand have always been an important part of the nation's environment. The earliest Maori settled and harvested shellfish and fin fish, including eels, from the coastal estuaries and lagoons, and collected material for weaving as well as snaring waterfowl from the flax swamps. Flax fibres from these flax swamps subsequently assumed economic importance, enabling establishment of the New Zealand settlement, and the extensive flat swamplands yielded fertile soil when drained, sustaining farmers and supporting sheep and dairy cows. Drainage became a major cultural activity, turning New Zealand into an economically productive land.

Consequently, few of New Zealand's native lowland wetlands remain intact, compromising their capacity to provide habitats for plants and other wildlife including rare species, natural landscapes, water storage systems and filtration plants for managing floods and water quality, and recreational pursuits like hunting waterfowl and fishing.

Development of the *New Zealand Wetlands Management Policy*

The *New Zealand Wetlands Management Policy* recognizes the difficulty of reversing this trend towards drainage for short-term gain. The situation at that time was exacerbated by little legislation for protecting wetlands yet a lot of policy and expertise facilitating their destruction, further compounded by the scattered nature of government agencies responsible for wetlands hampering coordinated policy.

Ratification of the *New Zealand Wetlands Policy* foreshadowed establishment of the Department of Conservation (http://doc.govt.nz/), which after vesting took a lead role in advocacy for wetland protection. Today, the Department for Conservation divides its roles with respect to New Zealand's natural environment, including its wetlands, into: protecting species; restoring places; monitoring; managing threats; and developing proposals (often in collaboration with others) for new parks, reserves and projects on conservation land. WERI, the national wetlands inventory, serves as the database for implementation of the *New Zealand Wetlands Policy*.

In approving the *Policy*, New Zealand's Cabinet Policy Committee noted "*. . .that the policy is intended to indicate that in broad terms the Government regards the protection of representative important wetlands as being desirable, rather than to bind the Government to any course of action or to justify restrictions on the actions of the private sector*". This is hardly the most ringing of endorsements of the need to preserve the broader values provided by the nation's dwindling wetland resource against a range of development pressures, though the statement has to be interpreted today in the context of the time in which it was made.

The *New Zealand Wetlands Management Policy*

The *New Zealand Wetlands Management Policy* defines wetlands as "*A collective term for permanently or intermittently wet land, shallow water and land-water margins. Wetlands may be fresh, brackish or saline, and are characterised in their natural state by plants or animals that are adapted to living in wet conditions*". It also recognizes the legacy of wetland loss, and with it the degradation of a range of beneficial hydrological, ecological, economic, recreational, educational and cultural services, noting that "*The need to preserve representative natural ecosystems already has public support and has been embodied in legislation*".

A number of key considerations are noted in the Policy, beyond the issues of public support and Government intent to offer wetlands – rare types of wetlands in particular – greater protection as noted above. These broader considerations include:

- Wetland management must consider causes and consequences beyond the wetland boundary;
- The long term benefits lost by modifying wetlands frequently do not justify the short term benefits gained; and
- Wetland modification may cause irreversible changes.

Objectives of the *New Zealand Wetlands Management Policy*

Three principal objectives are noted in the *New Zealand Wetlands Management Policy*, each supported by a range of sub-objectives. Quoting from the Policy document:

1. Preservation and Protection
   - To act urgently to protect by reservation additional wetlands that fulfil the criteria of the International Union for the Conservation of Nature and Natural Resources (IUCN) for Wetlands of International Importance.
   - To protect wetlands of national importance, and where appropriate, wetlands of regional and local importance.
   - To gain adequate permanent protection of representative examples of all types of wetland in private and public ownership. Priority will be given to preservation of the least modified and most ecologically viable examples of each kind.
   - To retain or re-establish wetlands significant for the protection or enhancement of aesthetic, scenic, recreational and tourism values.
   - To protect and manage habitats important for native flora and fauna, giving priority to rare and endangered species and habitats of importance to migratory bird species.
   - To protect, enhance, or re-establish wetlands and their access ways which are important for fish.
   - To promote the concept of managing all wetland catchments so that the complex relationships that exist within a wetland, and between a wetland and surrounding ecosystems, are taken into account.
   - To protect and manage wetlands that have an important hydrological role in such a way as to maintain or enhance that role.
2. Wetlands Inventory
   - To maintain an inventory of the most significant wetlands.
   - To link the national inventory for wetlands with other related government resource inventories to ensure optimal compatibility of the inventory.
3. Public Awareness
   - To promote public awareness of wetland values and encourage public participation in the planning and management of wetlands.
   - To preserve and enhance the opportunities afforded by wetlands for education, scientific study and recreation.
   - To promote the tourism and recreational potential of wetlands.

New Zealand's Department for Conservation today offers educational resources and other means for people to get involved with wetlands, including for example web pages dedicated to 'Wetlands Conservation' (Department for Conservation n.d.)

Next Steps

As noted in the *Introduction* of this chapter, the New Zealand Department of Conservation acknowledges that the current Policy has become outdated, and requires formal review. Nonetheless, interpretation of the *Policy* has evolved since its publication.

Conclusions

On publication, the *New Zealand Wetlands Management Policy 1986* constituted the first such national policy by a Contracting Party of the Ramsar Convention, recognizing long-standing losses to the nation's wetland resource and with them their substantial and diverse societal values. Measures put in place in the intervening years include institutional arrangements and use of emerging science. Today, the Department of Conservation recognizes the need to review the *Policy*.

National Wetland Policy: South Africa

104

John A. Dini and Mark Everard

Contents

Abstract

Recognising the scarcity, value and threatened status of its wetlands, South Africa has focused much energy on wetlands at the level of national policy in the last four decades. At the international level, South Africa was a founding member of the Ramsar Convention on Wetlands. The country opted not to develop a stand-alone wetland policy, but to incorporate objectives relating to wetland conservation and wise use into relevant sectoral policies, including those covering environment, agriculture, biodiversity, and water. Some of the tools to support the implementation of wetland-related policy are discussed, together with ongoing challenges.

Introduction

Wetlands mapped in South Africa to date cover a total area of 2.9 million ha or 2.4% of the country's surface area (Driver et al. 2012). This low extent of coverage is largely attributable to climatic conditions that are not conducive to the persistence of surface water. South Africa's average annual rainfall of 497 mm is well below the global average of 860 mm. Average annual potential evaporation over the majority of the country far exceeds rainfall.

Although wetlands make up such a small proportion of South Africa's surface area, they provide an array of valuable benefits to people. Many of these wetlands comprise natural infrastructure that assists in managing the country's limited water resources. Many also have biodiversity significance and are sites of spiritual, recreational, and scientific value. With climate change predicted to significantly alter South Africa's rainfall patterns (Knoesen et al. 2009), wetlands will play a more important role than ever before in mitigating the impacts of extreme events like floods and droughts. By providing highly productive opportunities for small-scale cultivation, as well as resources such as grazing, water, fish, fiber, and medicine, wetlands continue to underpin the health and livelihoods of many people in South Africa, especially poor rural communities.

Consistent with global trends, high levels of threat to the country's wetlands have been reported. The 2011National Biodiversity Assessment identified wetlands as the most threatened ecosystem type in South Africa (Driver et al. 2012). At least one third of indigenous freshwater fish are listed as threatened, and a recent study of the conservation status of fish, mollusks, dragonflies, crabs, and vascular plants in southern Africa reported far higher levels of threat in South Africa than in the rest of the region (Darwall et al. 2009). As a result of the limited extent of wetlands in South Africa, their loss and degradation will have more severe consequences than if the country was better endowed with larger and more extensive wetlands, particularly considering the context of South Africa as a semiarid country (Kotze et al. 1995).

Perhaps as a result of all these factors – scarcity, value, and threat – much energy has been focused on wetlands at the level of national policy in the last four decades. The current policy environment for wetlands is outlined further in the sections that follow, starting with relevant international agreements.

South Africa and the Ramsar Convention on Wetlands

At the international level, South Africa played a leading role in the formalization of the Ramsar Convention on Wetlands, becoming the fifth contracting party in 1975. The Convention entered into force the same year, following the accession of the seventh contracting party, and South Africa is thus considered a founding member.

The country's legal system is such that an international agreement like the Ramsar Convention must be transposed through the adoption at national and subnational levels of policy and legislative frameworks necessary to give effect to key elements of the Convention. For example, South Africa designates sites to the Ramsar List of Wetlands of International Importance, but these sites do not automatically receive protection under South African law simply by virtue of their Ramsar designation. Experience has shown that statutory protection is necessary if the country is to uphold its obligations under the convention in respect of these sites. For this reason, the Ramsar Administrative Authority in South Africa, the Department of Environmental Affairs, requires that sites proposed for Ramsar designation are proclaimed as a category of protected area under a legal instrument such as the National Environmental Management: Protected Areas Act.

Wetland-Related Policy in South Africa

The adoption and implementation of national wetland policies by contracting parties has emerged as a high priority for Ramsar, and much energy has been invested by the convention in encouraging the establishment of such policy frameworks at national and subnational levels (Bowman 2002). South Africa opted not to develop a standalone wetland policy, but to incorporate objectives relating to wetland conservation and wise use into relevant sectoral policies, including those covering environment, agriculture, biodiversity, and water. The "mainstreaming" of wetlands into those sectors with a high potential to impact on wetlands was considered to be the advantage of this approach. This made wetlands part of the business of these sectors, rather than creating a separate "wetlands sector" whose ownership was seen to lie with a traditional wetland champion like an environmental department.

As in other countries, agriculture has been one of the biggest drivers of wetland loss in South Africa (Kotze et al. 1995). It is therefore noteworthy that, for over a decade prior to the advent of the current suite of environmental and water legislation, the most powerful legal instrument to protect wetlands situated outside protected areas was the 1983 Conservation of Agricultural Resources Act. To this day, it remains a powerful legal tool for regulating the drainage and cultivation and utilization of vegetation in wetlands. The Act provides a clear mandate to the Department of Agriculture, Fisheries and Forestry (DAFF) with respect to wetland conservation and wise use, primarily from the perspective of ensuring the sustainable use of agricultural natural resources.

More recently, a range of other sectoral policy frameworks have incorporated wetlands. Government's environmental management policy (DEAT 1998) was formulated to give effect to constitutionally enshrined rights to an environment that is not harmful to health or well-being and that is protected for the benefit of present and future generations.

Framework legislation giving effect to these rights and principles was enacted in the form of the 1998 National Environmental Management Act. The Act places particular emphasis on "sensitive, vulnerable, highly dynamic or stressed ecosystems, such as coastal shores, estuaries, wetlands and similar systems," providing for specific attention to be given to these in management and planning procedures. Environmental impact assessment regulations published under the Act include a list of activities that have potentially significantly detrimental effects on the environment (DEA 2010). A number of activities pertaining directly or indirectly to wetlands are covered, including construction of aquaculture facilities, dams, canals, and infrastructure for water transfer; dredging, filling, and excavating in wetlands; and the extraction of peat.

Similarly, policy on the conservation and sustainable use of biodiversity (DEAT 1997) has been expressed in law through the enactment of the Biodiversity Act (2004) and Protected Areas Act (2003). The National Biodiversity Framework (DEAT 2009), published under the Biodiversity Act, provides a vehicle for coordinating and aligning efforts to conserve and manage South Africa's biodiversity. The establishment of a focused program to conserve freshwater biodiversity is listed as an urgent priority, together with other actions focused on implementing cross-sector policy objectives for conservation of freshwater biodiversity, incorporating biodiversity conservation objectives into the work of catchment management agencies, and placing emphasis on freshwater ecosystems in programs for ecosystem-based adaptation to climate change.

Perhaps most significantly from a policy perspective is national water policy (DWAF 1997) and one of its statutory expressions, the 1998 National Water Act. These were globally hailed as innovative and progressive for their explicit recognition that water resources are more than just water, that aquatic ecosystems comprise the resource base on which all other uses depend, and that healthy ecosystems underpin the sustainability of water use (Rowlston 2011). The Act contains three sets of Resource Directed Measures to protect aquatic ecosystems in order to secure ecologically sustainable development and use of water resources:

1. A system for classifying water resources (rivers, springs, wetlands, lakes, surface water, estuaries, and aquifers) into management classes, which in turn determine the balance between the use and protection of individual water resources. The system uses social, economic, and environmental criteria to identify which resources need protecting and which will be heavily used to accommodate social and economic needs.
2. The Ecological Reserve, which prescribes the minimum amount of water required to maintain the functioning of aquatic ecosystems, will vary according to the management class of the resource.
3. Associated with the management class of a water resource are a set of Resource Quality Objectives, which set out the quantity (including variability over time) and quality of water, assurance of instream flow, and character and condition of instream and riparian habitat and biota.

Supporting the Implementation of Policy

As is clear from the preceding discussion on wetland-related policies, the multifaceted and cross-cutting nature of wetlands requires what the South African Constitution terms "cooperative government" involving a wide range of sectors at multiple levels of governance. In order to deal with the reality of overlapping and sometimes conflicting sectoral policy mandates, the holders of these mandates jointly developed a set of cross-sector policy objectives for conserving South Africa's freshwater biodiversity. Under a common national goal for conserving freshwater biodiversity, a set of policy objectives has been articulated that collectively establish quantitative conservation targets for freshwater ecosystems, plan for representation and persistence of freshwater ecosystems, establish a portfolio of potential freshwater conservation areas, and support practical implementation (Roux et al. 2006).

A subsequent multipartner initiative elaborated on some of these objectives by producing maps of National Freshwater Ecosystem Priority Areas (NFEPAs). These maps constitute a single, nationally consistent information source of strategic spatial priorities for conserving freshwater ecosystems (Driver et al. 2011; Nel et al. 2011). The maps provide guidance on which rivers, wetlands, and estuaries should remain in a natural or near-natural condition to support the water resource protection goals of the National Water Act. They are also directly relevant to the listing of threatened freshwater ecosystems and bioregional planning processes provided for by the Biodiversity Act, and to the expansion of the protected area network through the Protected Areas Act.

Future Challenges

After two decades under a postapartheid constitutional dispensation, some hard realities are making themselves felt. The first is that South Africa is not short of policy. The problem lies primarily with implementation, rooted largely in insufficient resources and capacity, as well as weaknesses in the structures and practices of cooperative government.

This is particularly apparent with the National Water Act which, despite being hailed as a global forerunner, has proven difficult to implement. Resource Directed Measures have yet to be implemented across most of the country (Pienaar and King 2011). While much learning and preparatory work has been done since the Act's inception in 1998, the principal challenge ahead remains translating the Act's vision into action on the ground.

Overcoming these challenges will also require the employment of freshwater and wetland ecologists in the relevant government agencies (especially newly formed catchment management agencies) and municipalities to promote sustainable water development decisions.

Introduction

Taiwan is an island located to the west of Pacific Ocean and the southeast edge of Mainland China. Taiwan has a total area is 36,192 km^2. However, as much of the land comprises hills and mountains, only less than 40% of this land area is suitable for farming, industrial, urban, and rural development. Nevertheless, Taiwan is host to a diversity of types of wetland including high-mountain lake and other natural ponds, fishponds and irrigation systems, creeks, and rivers, in addition to coastal mudflats, marshes, lagoons, and mangroves. These different types of wetlands form a network of ecological corridors across Taiwan. Politically, a complexity arises in that sovereignty of the islands is contested, though it is generally recognized as being part of the Republic of China.

The Wetland Conservation Act (WCA), announced by the President Order on July 3, 2013, is the foundation of wetland management in Taiwan. Beside the regulations, the policies and actions of conserving wetland follow the guidance of "Taiwan's Wetlands of Importance Conservation Program (2011–2016)" that are based on the principle of wise use under the Ramsar Convention.

Background

Taiwan is situated on the earthquake belt where the Euro-Asia crust meets Pacific crust. It is the conflict of these crustal plates that creates the high mountain ranges of the small island. Every summer, typhoons bring in torrential rain, which washes soil and rocks into the island's creeks and rivers, its passage down to the ocean creates plains, forms ponds and lakes, irrigates paddies and farms, and deposits sediment on mudflats, lagoons, and mangrove stands along the coast. These diverse wetlands form a network that is closely connected with scrubland and forests, forming important ecological corridors across the island.

Due to the limited availability of land for human uses, population density and urban sprawl place significant pressure on environmentally sensitive areas including wetlands. (Census data from 2011 place the human population of Taiwan at 23,293,593, representing a population density on available land of 1609 per km^2.)

The first wave of wetland designations in 2007 in Taiwan recognized 75 wetlands of importance, with a further seven sites of wetland of importance recognized by January 2011. By the end of 2013, the number of wetlands of importance recognized in Taiwan numbered 83 sites. These include two sites considered to the of international importance: the Zengwun Estuary wetland and Sihcao wetland, within the Taijang National Park, which are the winter habitats of black-faced spoonbill (*Platalea minor*). There are an additional 40 wetland sites of national and 43 sites of regional importance, each of these sites performing different functions and with different targets for conservation such as management as wildlife refugia, for aquaculture, irrigation, urban recreation, sewage treatment, or/and flood management. The total area of these wetlands of importance comprises 56,860 ha.

Issues

In addition to the implications of climate change, Taiwan's wetlands are facing two principal threats: development and pollution.

Most of the wetlands in Taiwan are closely connected with people's daily life and lie close to rural or urban areas. The demands for land by industry and housing have caused many wetlands to have been filled and transformed for construction and development.

The second threat is pollution, especially for coastal wetlands. Formerly, wetlands were regarded and consequently treated as low value and marginal land and were commonly used as dumping grounds and sites for illegal waste management. This situation is common to many countries, not just in Taiwan, and has profound impacts not merely on the landscape but also for damage to coastal fisheries, food webs, ecology, and a host beneficial services.

Policy

Based on Article 18 of Taiwan's Basic Environment Act, "Government entities at all levels shall actively protect wildlife, ensure biodiversity, protect forests, estuaries and wetland environments, and maintain a diverse natural environment . . .." This is backed up by scientific support and environmental education. Taiwan's wetland policy includes three main aspects:

Building up the Regulation and Management System for Wetland

The Wetland Conservation Act (WCA), which was promulgated and announced by Presidential Order No. Hua-Zong-Yi-Yi 10200127201 on July 3, 2013, contains two core values: biodiversity and wise use. The Act comprises four parts:

(a) Assessment and designation of wetlands of importance
(b) Conservation and utilization plans for wetlands of importance
(c) Wise use management
(d) Development mitigation and ecological compensation

The Act is therefore the principal instrument for achieving wetland conservation and management in Taiwan.

Beside the WCA, there are connections with and cooperation in implementation of the Environmental Impact Assessment Act (EIA), Regional Plan Act (RPA), Urban Plan Act (UPA), and related land use management regulations are also important and necessary in supporting wetland management. The key challenge is to incorporate the spirit of wise use into these regulations.

Developing Financial Tools and Creating Market Mechanisms for Wetlands

Wetlands support the provision of food, water resources, recreation, and many other dimensions of well-being for people's daily lives in Taiwan. Thus, using market mechanisms to support wetland conservation has significant potential in terms of internalizing these often formerly overlooked values. There may be potential for creation of internal markets, for example where a proportion of profits from products derived from wetlands, especially related to agricultural production, could be recirculated to promote wetland conservation and hence resource sustainability.

Central government budgets also recognize the importance of wetland conservation, with a three-year program of support and cooperation with local government bodies, colleges, NGOs, and communities for wetland conservation programs and activities. This strategy has proven effective for promoting private sector and public awareness and interest in addressing wetland issues and conservation.

Given the global financial situation, and specifically its tightening of public finances, Taiwan is seeking funds from these novel market mechanisms as a partial replacement for central government support.

Using Environmental and Land Use Planning Tools to Preserve Wetlands and Form Ecological Corridors

Wetlands are a key element of the ecological corridors across Taiwan, linking with forest, bush, and urban open space habitats. The concept of a "green belt" is worth progressing, and may in time form a key tool is the spatial planning system.

Taiwan's strategy for development of a green belt is to preserve forest, bush, and natural wetland resources, including designation of wetlands of importance, as well as promoting more environmentally sensitive paddy field management. There is also interest in investment in constructed wetlands, which may help address flood risk management, urban recreation, pollution control, and a range of other environmental values. Wetland systems play important roles in supporting a range of beneficial services and so, as part of a network of ecological corridors, need to become incorporated into regional planning processes. The spirit of wise use will be fulfilled when wetland site management is integrated within a wider approach to urban land use and wider spatial planning.

Future Challenges

Although the WCA was announced in 2013, its development will face continuing resistance from a range of stakeholders including challenges from developers. For example, concerted representations from construction, real estate, fishery, agriculture, and other interests could limited the potential of the Act to protect wetlands of importance and the efficacy of related regulations. Possible solutions to this potential outcome include implementing appropriate mechanisms, such as agreed methods of management or building codes, that are not only science-based but also embody the spirit and principle of wise use.

Incorporating ecosystem management into market mechanisms also represents a significant opportunity for natural resource management. Although wetlands have many associated use and nonuse services, offering direct and indirect benefits for human society, a few, except some physical products, have current market values assigned to them. Other wetland values may be amenable to assigning market prices, including for example the links between wetland fauna and cultural creativity which may offer inducements for wetland conservation. Extension of market mechanisms to nontraditional wetland services needs considerably more research.

Finally, it is important to educate and influence wider sectors of the public about the importance of wetlands in supporting their well-being, in addition to the inherent and ethical values of protecting habitats and wildlife for future generations. Understanding how best to connect these values with those held by people of different groups and ages requires more fundamental research if Taiwan's wetlands and their services are to become mainstream societal concerns.

Contents

Abstract

Uganda's wetlands are widespread and complex. Wetlands cover an estimated 13% of Uganda's land surface, constituting the most widespread ecosystem type in the country. Uganda's wetlands contribute immensely to people's livelihoods and to the health of the environment, through processes such as water storage and purification, products obtained from ecosystems, benefits from regulation of ecosystem services, nonmaterial benefits obtained from ecosystems, and services necessary for the production of all other ecosystem services.

Introduction

Uganda's wetlands are widespread and complex. Wetlands cover an estimated 13% of Uganda's land surface, constituting the most widespread ecosystem type in the country. Uganda's wetlands contribute immensely to people's livelihoods and to the health of the environment, through processes such as water storage and purification, products obtained from ecosystems, benefits from regulation of ecosystem services, nonmaterial benefits obtained from ecosystems, and services necessary for the production of all other ecosystem services.

Derivation of the Uganda National Wetlands Policy

An officially recognized National Wetlands Policy is an essential step towards the sustainable management of wetlands in Uganda and was the main thrust during the first four years of existence of Uganda's National Wetlands Programme. With hindsight, it is clear that the time and human resource requirements necessary for the process of developing the National Wetlands Policy were severely underestimated.

In Uganda, wetlands policy development started with very little political support, awareness, and information. Rushing policy development under such circumstances runs the risk of creating a document that has little support beyond its initiators, and which may not be realistic in terms of its objectives and implementation mechanisms. However, postponing publication of a wetlands policy until the whole country is behind the idea, and when all relevant information has been collected and digested, would result in unhelpful delays, potentially including postponing policy development indefinitely.

From the outset, wetland management efforts were directed towards policy formulation and development, and development of a specific institutional framework for wetland management. The need to establish a specific institution and legislation for wetland management came with the Policy on *No Further Drainage,* declared in 1986 by His Excellency the President of Uganda. This pronouncement came against a backdrop of rampant degradation, which was proceeding unabated at the time.

In 1989, the Uganda Government established the National Wetlands Conservation and Management Programme (NWP) to develop policies and implementation strategies for the sustainable management of Uganda's wetlands. This came in the wake of a slowly emerging realization in Government circles and civil society that wetlands are extremely important ecosystems that contribute considerably to the national economy and rural livelihoods.

The Uganda National Wetlands Policy was adopted in 1994, making Uganda the first country in Africa to adopt a national wetlands policy.

The Aims, Principles and Strategies of Uganda's National Wetlands Policy

The Uganda National Wetlands Policy aims at promoting the conservation of Uganda's wetlands in order to sustain their ecological and socioeconomic values for the present and future wellbeing of the people. In support of this aim, the National Wetlands Policy sets five goals:

- To establish the principles by which wetland resources can be optimally used now and in the future
- To end practices which reduce wetland productivity
- To maintain the biological diversity of natural or seminatural wetlands
- To maintain wetland functions and values
- To integrate wetland concerns into the planning and decision making of other sectors

Three principles apply in pursuit of these goals:

- Wetland resources form an integral part of the environment and their management must be pursued in the context of interaction between conservation and the national development strategies and activities.
- Wetland conservation can best be achieved through a coordinated and cooperative approach involving all stakeholders.
- It is of vital importance for wetland conservation and management that current attitudes and perception of Ugandans regarding wetlands are changed.

The National Wetlands Policy lays out several strategies to achieve the policy goal. These include, but are not limited to, the following:

- Ensuring that there is no drainage of wetlands unless more urgent environment requirements supersede
- Ensuring that only non-destructive activities are carried out in and around wetlands
- Ensuring that wetland developments are subject to environment impact assessment and environment audits
- Maintaining an optimum diversity of uses and consideration of other stakeholders when using a wetland

Successes Under the National Wetlands Policy

More than 20 years of work in wetlands management has greatly increased understanding of how wetland ecosystems work, and what they do for local users and the country as a whole. This has lead to the conclusion that wetland ecosystems in

Uganda must be recognized as a vital natural resources sector, very similar to forests or agriculture.

Success has been registered in wetland conservation and management. There is increased awareness of wetlands, and wetlands are now high on the political and public agenda as exemplified by the debates in cabinet and parliament as well as the coverage in both print and electronic media. Wetlands of Uganda have also been mapped and an inventory has been completed, and wetland issues have been incorporated into key legislation such as the Constitution of 1995, the National Environment Act of 1995, and the Land Act of 1998. Community participation remains a key tool used by the department to promote best use guidelines and designation of Ramsar sites. There is also increased reporting of wetland abuse cases, and more people are seeking guidance on how to manage wetlands.

However, success notwithstanding, challenges still exist due to the complex tenure and ownership of land, weak enforcement of the law, a narrow knowledge base, conflicting interests, the effects of climate change, development and population pressure, and disregard of environmental laws with impunity. To address these challenges, a new strategic direction 2011–2020 has been developed and is intended to focus on enhancing the productivity and service provision of wetlands, strengthening of regulatory frameworks and equity in stewardship, strengthening institutional and technical capacity, enhancing public and stakeholder awareness, and encouraging participation in wetland management and resource mobilization.

So has the policy worked? An official Wetland Policy is a declaration of intent to develop legislation, but of itself carries no legal weight as far as enforcement is concerned. Uganda was fortunate in that, between 1995 and 1998, an array of important laws were produced, which created the opportunity to insert wetland clauses into key legislation. Between 1995 and 1998, wetland clauses were incorporated into the National Environment Statute (1995), the Constitution (1995), the Local Government Act (1997), and the Land Act (1998).

This quick succession of laws and attendant wetland clauses gave the National Wetlands Policy statutory "muscle." It also created, however, a certain level of confusion, notably on the status of wetlands as a natural resource. This first started when the Constitution (1995) vested "*...the ownership of land in the people of Uganda,*" but also stated that "*...wetlands...shall be held in trust by the government for the common good of all people.*" This trustee doctrine has put wetlands in the same class of natural resources as forest reserves, rivers, lakes, and national parks. At first glance, this would seem to be a tremendous opportunity for strict wetland management. However, Uganda is today still grappling with the full implications of this situation. Large tracts of Uganda's seasonal wetlands are managed under customary management regimes, either as common or individual property. The new Constitution takes the management responsibility away from the original "owners" and vests it in a trustee, which as yet remains unidentified.

Important Lessons Learnt

A number of lessons have been generated and learnt during the policy development process. Key among these is the fact that wetland development is a long-term process. The initial plan was to have a 2-year project to develop the National Wetlands Policy. As it turned out, the policy was adopted 4 years and 20 years on, and implementation continues. Development of the scientific and socioeconomic knowledge base takes time, money, and effort, but is important in informing decision-making processes, and requires continued targeted, specific, and general awareness-raising. Engagement of all relevant stakeholders is also key to successful interventions. Effective implementation of laws and the functioning of associated institutions require adequate human and financial resources. Policy and institutional harmonization is also key to strengthening operations, political will and support is vital to successful program, and land ownership issues must be clarified from the outset if effective enforcement is to be realized.

Furthermore, communities cannot conserve wetlands without economically viable livelihood options, incentives, and benefits. In other words, there is a need to have "linked enterprises": enterprises which will make people love and value the natural resources. These linked enterprises, for example ecotourism and measures such as catchment-related activities which contribute to soil and water conservation and the introduction of piggeries and goat-keeping in the catchment, need to be economically viable and also deliberately to reduce pressure on natural resources, specifically including wetlands. Cross-sectoral collaboration and increased engagement with relevant legal and management institutions and capacity development are key to institutional sustainability. It is also important to create political and public interest by using the right arguments, leading to the acceptance of modified user systems and co-opting as many organizations as possible.

In conclusion, wetlands in Uganda are vast, complex, and extremely valuable ecosystems. Their value is derived not so much from the products they deliver to the resource user, but from the hydrological and ecological services they provide almost unnoticed. However, planners, economists, and politicians usually have no idea what wetlands do for the economy, public health, or the prosperity of their countries. They often see wetlands only as valuable land for conversion for agriculture, industrial estates, or urban development, and believe that they can do away with these wetlands through infilling or channeling water. Local users, on the other hand, may have a better understanding of the value of wetland products, but that understanding does not necessarily lead to sustainable wetland use since maximizing outputs of a few products may result in the collapse of the whole system, and notably its broader set of ecosystem services. Misconceptions about wetlands are so deep and widespread that turning people away from wetland degradation is not easy and requires a long-term outlook, including considerable persistence, creativity, and resources. However, the task is far from impossible.

The tremendous work accomplished in the area of wetland conservation and management in Uganda has been a motivating and evolving process, which has made Uganda a frontrunner, not only in Africa but the world over. Currently, many countries across the world are keen on benefiting from our rich and informative experience. For this purpose, the Ramsar Centre for Eastern Africa (RAMCEA) has been established to build capacity of wetland managers and practitioners.

Certainly, as Uganda continues this learning journey, which started with a political pronouncement on “No further drainage of Wetlands,” we are now more confident that almost two decades of wetland conservation provide the benchmark for future success. In addition, the upgrading of what started out as a National Wetlands Programme, now constituting a fully fledged Wetlands Management Department, makes the task ahead much easier in the knowledge that more stakeholders are informed and willing to join the battle to jealously guard and protect our wetlands through the promotion of their wise use.

Introduction

United States wetland policy has developed over the past four decades. Prior to the 1970s, government policy largely reflected the view of wetlands as unproductive swampland that posed a nuisance to human health. The Swamp Lands Acts of 1849, 1850, and 1860, for example, provided states with control over large wetland areas in order to promote their drainage and repurposing for use in agriculture. Concern about wetland loss emerged only after its negative impacts to fish and waterfowl became apparent, in part due to federal laws such as the Fish and Wildlife Coordination Act of 1934 and the US Fish and Wildlife Wetlands Inventories of 1954 and 1973 (National Research Council 1992). This policy of promoting or not restricting wetland conversion lead to the loss of more than 50% of total wetland acreage in the contiguous United States over a 200-year period ending in 1980 (Dahl 1990).

In 1972, the US Congress passed the Clean Water Act, amending an existing law to create what remains the lynchpin of federal wetlands policy. Under the Clean Water Act, two federal agencies, the Environmental Protection Agency (the EPA) and the Army Corps of Engineers, are jointly charged with administering a permitting program that prohibits the conversion of protected wetlands unless certain conditions are met. As understanding of the importance of wetlands grew, a broad range of other federal legislation and programs advancing wetlands protection emerged. By 1987, as the rate of wetland loss had slowed but not halted, the EPA requested a nongovernment organization, Conservation Foundation, to convene a forum of government, business, academic, and NGO stakeholders to address how the nation should protect and manage its wetlands. The forum issued as its key recommendation that national policy be guided by the goal of "no net loss" of remaining wetlands, and this policy has become the defining feature of US wetland management. President George HW Bush adopted the no net loss policy in 1989, and subsequent administrations have each endorsed the goal.

Despite adoption of a clear "no net loss" objective, US wetlands management policy has had mixed results. From an average loss of 458,000 acres of wetland per year during the 1950s–1970s, annual losses dropped to 290,000 acres from the mid-1970s to mid-1980s, and more dramatically to 58,500 acres from 1986 to 1997 (Dahl 2006). From 1998 to 2004, wetland acreage *increased* an average 32,000 acres per year. This net growth, however, reversed from 2004 to 2009, with wetland conversion again slightly outpacing wetland creation and restoration for a net loss of an estimated 62,300 acres during the 5-year period. These figures do not capture regional trends in wetland loss, changes in wetlands quality or functionality, or shifts in wetland types, which are also important indicators of the success of wetland policy (Dahl 2011).

Key Features of U.S. Wetland Policy

Limits on Federal Jurisdiction

Federal authority to regulate wetlands is limited because the US Constitution provides only certain enumerated powers to the federal government and retains the balance of authority to State governments. Federal authority to manage wetlands stems from its power to regulate interstate commerce. While the law is somewhat in flux, in general, the federal government may assert jurisdiction over wetlands if those wetlands, alone or in combination with similarly situated wetlands, significantly affect a waterway traditionally subject to federal jurisdiction (i.e., navigable waters that historically served as conduits for interstate commerce). The US Supreme Court established the operable test for federal jurisdiction over wetlands in a 2006 decision (Rapanos v. United States). Because the current test does not provide clear, categorical guidance as to which wetlands are jurisdictional, dispute has arisen surrounding federal agencies' assertion of regulatory authority over isolated or ephemeral hydrological features like ponds, intermittent streams and remote wetlands. The EPA and the Army Corps of Engineers recently proposed a regulation that is expected to clarify the limits of federal jurisdiction.

Under the US federal system of government, states retain an important role in wetlands management. States often exercise regulatory authorities that can critically impact wetlands, including potentially authority over isolated wetlands outside of federal jurisdiction. State agencies frequently implement wetlands management programs, while federal programs provide support for such activities through grants or information-sharing. States also play a direct role in the federal permitting program, by certifying a proposed permit will comply with state water quality standards and establishing coastal zone management programs with which federal actions, including permits, must be consistent.

Federal Agencies

There is no single federal agency responsible for US wetland policy. Instead, a large variety of agencies have regulatory authority over or implement programs affecting different aspects of wetland policy.

The Clean Water Act

The Clean Water Act is the most important federal tool to advance national wetland policy. The Act's purpose is broadly "to restore and maintain the chemical, physical, and biological integrity of the Nation's waters", Section 404 of the Act establishes a permitting regime to regulate the filling of US waters, including wetlands under federal jurisdiction. In order to receive a permit, an applicant must demonstrate to the Army Corps of Engineers that its proposed discharge (i.e., the activity resulting from the drainage or filling of a wetland) complies with what are known as the "404(b)(1) Guidelines". Assuming these guidelines are met, the Army Corps of Engineers will grant the permit unless it finds the permit to be contrary to public interest.

The 404(b)(1) guidelines aim at prohibiting a discharge unless it is demonstrated that it will not have unacceptable impacts on the aquatic ecosystem. A permit applicant must show that its proposed discharge is the least environmentally damaging practicable alternative to achieve the purpose of a project. (For example, a highway scheme may be required to result in the destruction of the smallest number of wetlands to provide desired public transit, given economic and technical constraints.) If a project does not depend on being sited within wetlands or in proximity to water, the Army Corps of Engineers assumes that such a practicable alternative is available unless a permit applicant clearly demonstrates otherwise. A permit will not be granted if the discharge has certain adverse effects, such as contributing to a violation of water quality standards or threatening an endangered species. Even if these conditions are met, a permit will not be granted unless the project takes practicable steps to minimize the harm it causes to the aquatic environment. In addition to the direct impacts of the discharge on wetlands, the agency must consider the cumulative impacts of other discharges on the ecosystem (for example, whether filling only a small quantity of wetland nonetheless impacts the quality of the water environment because it has already been severely impacted) and the secondary impacts of the project (such as the indirect impacts caused by building a road due to increased access to the environment) before issuing a permit.

Once all practicable steps to avoid adverse impact have been incorporated into the proposed activity, the Army Corps of Engineers requires mitigation for unavoidable impacts. Such compensatory mitigation may include restoration, creation, enhancement, and preservation of aquatic resources through a number of means. In 2008, the Army Corps of Engineers adopted new regulation intended to improve the success of compensatory mitigation by promoting a focus on the watershed and encouraging the use of ecological performance measures.

Federal Funding

In addition to direct regulation, a large number of federal laws provide funds or withhold federal benefits in order to promote the protection or restoration of wetlands. Other federal laws designate wetlands for particular protection.

Water Resources Development Act of 2000 (P.L. 106-541)	USACE	States that future mitigation plans for federal water projects should include "in kind" mitigation for bottomland hardwood forests
Wetlands Loan Act (1961) (P.L. 87-383	FWS	Provides interest-free loans for wetland acquisition and easements.
Wild and Scenic Rivers Act (P.L. 90-542) (1968)	DOI, USDA	Protects designated river segments from alterations without a permit

Future Challenges

The proposed EPA/Army Corps of Engineers rule may improve clarity over the scope of federal jurisdiction; however its effects are uncertain until the rule is finalized. The process to finalize the rule and then observe whether it survives legal challenge in court is likely to span several years, during which the legal uncertainty surrounding the limits of federal authority will remain a barrier to federal enforcement efforts.

Due to the limits on federal authority to regulate certain wetlands, the patchwork and divergent approach of state regulators remains a continued challenge to wetlands protection. Many states lack strong legislation to protect wetlands or fail to enforce laws already in place.

Controls over stormwater runoff, which may adversely impact wetlands due to pollutant loads, remain an evolving area of the law. Certain areas of the USA. are exploring novel methods to control runoff, but attaining widespread implementation of such controls remains a challenge.

Finally, failed mitigation represents a serious challenge to attainment of national wetlands policy. Despite federal efforts to reform wetland mitigation requirements to ensure that there is no net loss of wetland functionality due to approved projects, there remains concern that mitigation requirements are imperfectly designed and inadequately monitored, and that full compliance is not being attained.

No Net Loss: Overview

108

Mark Everard

Contents

Abstract

The concept of No Net Loss relates to the principle under which counties, agencies, and governments strive to balance unavoidable habitat, environmental and resource losses, with replacement of those items on a project-by-project basis so that further reductions to resources may be prevented. No Net Loss is a bold and attractive proposition, which is gaining traction in addressing wetland and other environmental management challenges globally. However, its practical implementation is fraught with difficulties and the potential for derailment by vested interests. More robust and operationally applicable methods are required to assess the diversity of functions and socially valuable services provided by wetlands if their net contributions to society are to be fully assessed and factored into decision-making about the avoidance, mitigation, or compensation of wetland loss.

Introduction

The concept of No Net Loss relates to the principle under which counties, agencies, and governments strive to balance unavoidable habitat, environmental and resource losses, with replacement of those items on a project-by-project basis so that further reductions to resources may be prevented (EU 2014a).

No Net Loss policies have been applied to a wide range of environmental issues. One example is its application to water balance in the Lower Colorado River Basin in Texas under the House Bill (HB) 1437 Agriculture Water Conservation Program, offering an innovative way to conserve water, meet rising municipal demands, and maintain agricultural productivity (LCRA n.d.) Requirements to avoid damage to Natura 2000 sites across the European Union, designated under the EU Birds Directive, the EU Habitats Directive, and the EU Environmental Liability Directive, also require habitat replacement where losses are "unavoidable" constituting a broader No Net Loss approach to wildlife habitat.

However, the No Net Loss policy is most widely known in the field of wetland protection, safeguarding both the environment and public access to it. Across the USA, No Net Loss has been the key policy in wetlands protection at both the federal and state level, instigated during the presidency of George H.W. Bush during which time each State administration adopted the "no net loss of wetlands" policy (White House Office on Environmental Policy 1993).

The US No Net Loss Policy Concerning Wetlands

Since the eighteenth century, wetland area has decreased from nearly 220 million acres (890,000 km^2) in the lower 48 states of the USA to 107,700,000 acres (436,000 km^2) in 2004, leaving approximately 100 million acres (400,000 km^2) of wetlands (Dahl and Allord 1997). Since the 1950s, over 50% of this loss has come from wetlands being transitioned to agricultural lands (Hansen 2006). Wetland loss is also driven by other factors including development and forestry.

No Net Loss is the United States government's overarching policy goal regarding wetland preservation. The goal of the policy is to balance wetland loss due to economic development with wetlands reclamation, mitigation, and restoration such that the total acreage of wetlands in the country does not, at worst, decrease but rather remains constant or increases (Sibbing n.d.)

Barriers to implementation are numerous. In part, these stem from the fact that some 70% of wetlands are on private landholdings, requiring a partnership-based approach. Politically, influential groups can lobby or otherwise use their leverage to receive exemptions. Economically, the magnitude of opportunity costs associated with foregone profit from agriculture and development can and are used to justify wetland conversion, though the extent to which this actually takes account of losses of the broad beneficial hydrological, cultural, ecological, and other ecosystem services provided by a wetland is moot. In addition, the technical difficulty of wetland recreation is generally underestimated, while the functional equivalence of compensatory wetlands is rarely addressed.

No Net Loss in the EU

Recognizing that the target of halting biodiversity loss by 2010 had not been achieved across the European Union, with many species and habitats continuing to decline significantly, the EU (EU 2014a, b) has accepted the value of a No Net Loss policy. However, there is at present no requirement for compensation of unavoidable residual impacts outside species and habitats covered by nature legislation, regardless of their loss.

There is therefore a need for further action to promote a wider No Net Loss approach to biodiversity and ecosystem services to achieve the overall objective of the *EU Biodiversity Strategy to 2020* (EU 2012) to halt biodiversity and ecosystem service loss by 2020. Action 7 under target 2 of the *EU Biodiversity Strategy to 2020* seeks to "...ensure no net loss of biodiversity and ecosystem services." Action 7 comprises two complementary subactions:

- Action 7a foresees that "...in collaboration with the Member States, the Commission will develop a methodology for assessing the impacts of EU funded projects, plans and programmes on biodiversity by 2014." This recognizes the need for "biodiversity proofing" the EU budget to ensure that spending under the EU budget has no negative impacts on biodiversity and that it is overall supportive of achieving the biodiversity targets.
- Action 7b specifies that "...the Commission will carry out further work with a view to proposing by 2015 an initiative to ensure there is no net loss of ecosystems and their services (e.g. through compensation or offsetting schemes)."

As in most jurisdictions today, these bold statements in Europe are subsumed within an economic growth agenda. This is both a threat and an opportunity. For example, the EU's (2011) *A Roadmap to a Resource Efficient Europe* explicitly refers to the "...innovation potential of Green Infrastructure and the 'restoration economy'...," which may provide a means for increasing recognition of the multiple ecosystem service benefits flowing from wetlands and other habitats to be internalized into economic decision-making. Following an ongoing (at the time of writing) consultation exercise on *Halting biodiversity loss – the EU no net loss initiative* (EU 2014a,b), an EU No Net Loss initiative is expected in 2015.

How Does the No Net Loss of Wetlands Policy Work?

As a minimum, a No Net Loss strategy aims to maintain a minimum area of wetland throughout a state or other political land unit. However, because of the increasing demands for population and development, this wetland resource is under increasing pressure. In the USA, various instruments are applied at federal, state, and local levels to achieve the objective of No Net Loss. These include command-and-control regulation, principally under the Clean Water Act, market-based instruments (including, for example, the Swampbuster programme), catchment management strategies, stakeholder involvement, and wetlands mitigation banking.

The "avoid-mitigate-compensate" sequence is one of the ways in which this is being addressed. As its name suggests, the first approach should be to avoid damage to a wetland, for example, by siting a proposed development elsewhere or changing its design fundamentally. The second tier of approach is then to seek to mitigate harm from the development proposal. The third is provision of compensatory habitat, whether locally or more remotely, and may include wetland restoration, creation, enhancement, and reallocation.

There are major challenges in the construction and management of compensatory wetland habitat. For example, while creation of a wetted area of roughly the same size is less challenging, producing a wetland of the same character and function is far more difficult. This difficulty increases incrementally as more of the ecosystem services produced by wetlands are taken into account. For example, does the new constructed habitat have the same ecological characteristics as that which it is assumed to replace, playing host to the same biodiversity and natural processes? Is it sited such that it will still serve a valuable role in migratory flyways and other means by which species translocate across landscapes? Will it perform the same range of valuable hydrological, geochemical, educational, recreational, aesthetic, and other ecosystem services? And how do we measure these diverse parameters pragmatically, intuitively, and unequivocally in an operational context? The ► Chap. 110, "No Net Loss Case Study: Wetland Banking in Chicago (USA)" chapter highlights how ineffective wetland compensation is in general across the USA. The same observations apply equally to wetland mitigation.

Conclusions and Challenges Remaining

No Net Loss is a bold and attractive proposition, which is gaining traction in addressing wetland and other environmental management challenges globally. However, its practical implementation is fraught with difficulties and the potential for derailment by vested interests. More robust and operationally applicable methods are required to assess the diversity of functions and socially valuable services provided by wetlands if their net contributions to society are to be fully assessed and factored into decision-making about the avoidance, mitigation, or compensation of wetland loss. There are also substantial gaps in political and business understanding of how these functions and services support economic and other facets of societal progress, the dominant perception still evidently remaining that wetland conservation is a constraint on progress rather than a sound investment in underpinning capital vital for future wellbeing including economic prospects.

For a No Net Loss policy to be fully effective, realistic and economically relevant metrics (including persuasive valuation of wider nonmonetary contributions to society) need to be developed to demonstrate the multiple wider values provided by wetlands and how these factor into economic progress. At present, No Net Loss appears not to be being achieved, and so the progressive decline of natural capital and future security continues to the detriment of future prospects and security.

109 No Net Loss Case Study: Structural and Functional Equivalence of Mitigation Wetlands

M. Siobhan Fennessy and Abby Rokosch Dresser

Contents

Abstract

Sections 401 and 404 of the Clean Water Act require that wetlands in the United States must be created or restored as "replacement" or "mitigation" wetlands in order to compensate for wetland areas that are lost due to development. This is in order to meet the US policy mandating a "no net loss" of wetland extent or function by balancing the need for economic development with wetland preservation. A question related to this policy is whether or not mitigation wetlands are structurally and functionally equivalent, to those they are designed to replace. In other words, is wetland mitigation a fair trade? The uncertainty in whether mitigation wetlands can succeed in replacing natural sites has led them to be called a "large-scale ecological experiment."

Introduction

Sections 401 and 404 of the Clean Water Act require that wetlands in the United States must be created or restored as "replacement" or "mitigation" wetlands in order to compensate for wetland areas that are lost due to development. This is in order to meet the US policy mandating a "no net loss" of wetland extent or function by balancing the need for economic development with wetland preservation (Zedler 1996; NRC 2001; Burgin 2010). A question related to this policy is whether or not mitigation wetlands are structurally and functionally equivalent, to those they are designed to replace (Matthews and Endress 2008; Moreno-Mateos et al. 2012; Stefanik and Mitsch 2012). In other words, is wetland mitigation a fair trade? The uncertainty in whether mitigation wetlands can succeed in replacing natural sites has led them to be called a "large-scale ecological experiment."

Mitigation projects are classified as creation, restoration, or enhancement according to the approach used in project design. Wetland creation is defined as the conversion of uplands to wetlands, while restoration is the reestablishment of a wetland where one had existed in the past. Enhancement refers to an increase in the ecological condition of an existing wetland. In wetland mitigation, restoration projects are often found to be more successful. This is largely due to the higher probability that hydric soils, a seed bank, and appropriate hydrological conditions will be present at the site.

The goal of the case study presented here was to do a comprehensive investigation of a set of natural ($n = 9$) and mitigation wetlands ($n = 10$) located in Ohio, USA, in order to determine whether the mitigation sites were similar to natural wetlands in terms of their hydrology, soils, and vegetation (a full description of all aspects of this study can be found in the original report, Fennessy et al. 2004). As part of our analysis, we employed vegetation-based biological assessment tools to quantify the differences in the ecological condition of the sites. We assumed that if the hydrology, soil characteristics, and plant community structure of the mitigation sites were similar to natural sites, then they would also function similarly; thus they would have equivalent ecosystem structure and function, a tenet of the no net loss policy.

When selecting the natural sites we considered the hydrogeomorphic class (Brinson 1993), dominant vegetation type, relative degree of disturbance, and site access. All natural wetlands were mixed emergent marshes that spanned a gradient of disturbance from those highly impacted by human activities to those least impacted. Nine of the created wetlands were mitigation projects, created due to individual CWA Section 401/404 permits, and were selected to represent sites aged between 1 and 10 years. The 10th was created under the Natural Resources Conservation Service Wetlands Reserve Program.

Methods

We used an ecosystem level approach to assess the components and processes that are most likely to: (1) illustrate differences between the two types of wetlands and assess whether mitigation was meeting the net loss goal in terms of wetland structure (e.g., vegetation and soil characteristics) and function (primary productivity, hydrology exchanges); (2) make recommendations that might improve the success of mitigation projects; and (3) establish indicators suitable for use as performance standards (Fig. 1). Data were collected during one growing season (May–September). Complete descriptions of field and laboratory methods are described in Fennessy et al. 2004.

Results and Discussion

Hydrology

Natural and created wetlands had significant hydrological differences (Fig. 2). Created wetlands had deeper surface water levels (data not shown), greater mean depth to groundwater, and a shorter duration of water in the root zone (top 30 cm of soil profile). Surface water depths (measured at the deepest part of the wetland) averaged 29.5 cm in the natural and 43.7 cm in the mitigation wetlands. Groundwater levels were found in the root zone 55% of the time in natural sites and only 22% of the time in mitigation sites.

The high bulk density of the mitigation site soils is a likely cause of the hydrologic differences between the wetland types (see Table 1). High bulk density limits water movement through the soil, and may have contributed to the hydrological differences noted, including the relatively short duration of water in the root zone and the lack of a draw down period in the mitigation sites.

The combination of deeper surface water and lower groundwater levels in created sites has implications for plant growth, community development (water available for root uptake; successional processes), and biogeochemical processes, for example, denitrification. In this case, the relative lack of water movement limits the delivery of compounds such as nitrate and dissolved organic carbon needed by denitrifying microbes. Ultimately, improper hydrology seems to limit the development and function of the mitigation sites towards a more natural wetland condition.

Soils

Overall, soil characteristics were significantly different in the mitigation sites (Table 1). Soil organic carbon (%) was nearly five times greater ($p = 0.007$) in natural than mitigation sites, averaging 15.1+3.2 and 3.1+0.64%, respectively. Concentrations of percent soil nitrogen ($p = 0.008$) and plant available phosphorus (μgP/g soil; $p = 0.08$) were also significantly higher in the natural sites. The soil composition of

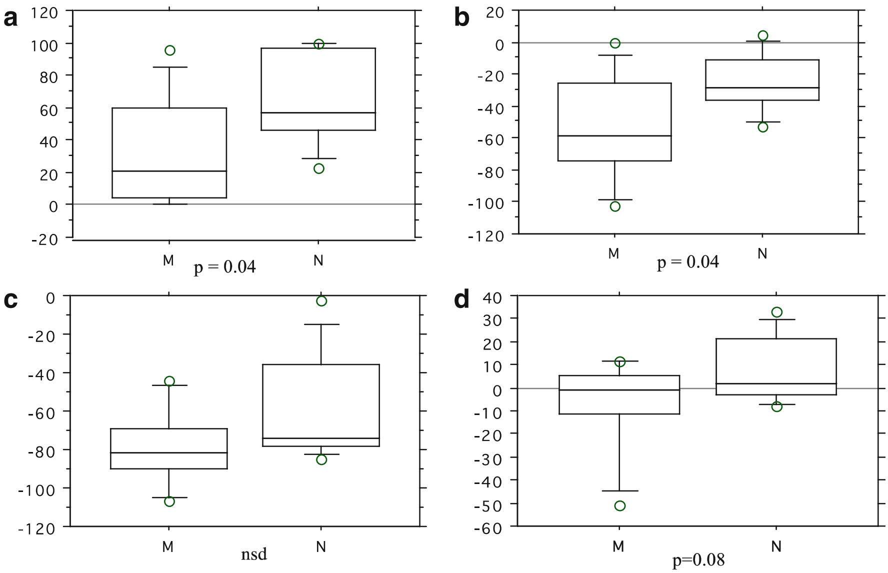

Fig. 2 Box plots for four hydrological parameters for mitigation versus natural wetlands during the growing season (May–September). Parameters are: (**a**) percent time groundwater was in the root zone (top 30 cm of soil profile), (**b**) mean depth to groundwater (cm), (**c**) mean maximum depth (cm), and (**d**) mean minimum depth to groundwater (cm). Positive values in **b**–**d** indicate water levels were above the soil surface. Means were evaluated using unpaired t-tests (p values shown)

Table 1 Summary of mean soil parameters for natural and mitigation wetlands. Values recoded are an average of five replicates in each of the nine natural sites and 10 mitigation sites (mean ± SE). P-values show results of a two-sample T-test to determine if means are significantly different (From Fennessy et al. 2004)

Soil parameter	Natural	Mitigation	p-value
pH	5.42 ± 0.17	6.29 ± 0.22	0.006
% Organic carbon	15.1 ± 3.2	3.1 ± 0.64	0.007
% Nitrogen	1.13 ± 0.24	0.26 ± 0.03	0.008
Plant available P (μg/g)	12.2 ± 1.1	7.4 ± 2.3	0.08
Bulk density (g/cm^3)	0.62 ± 0.13	1.75 ± 0.15	0.001
% Solids	42.5 ± 6.0	73.6 ± 1.5	0.001
Ammonia (ug/g)	62.4 ± 15.3	20.5 ± 3.3	0.01
P total (ug/g)	1156 ± 252	669 ± 91	0.07
Exchangeable Ca (ug Ca^{2+}/g)	10897 ± 3585	8705 ± 3700	NS
Exchangeable Mg (ug Mg^{2+}/g)	3600 ± 700	5401 ± 1602	NS
Exchangeable K (ug K^+/g)	5501 ± 1384	5155 ± 733	NS
Exchangeable Na (ug Na^+/g)	2612 ± 581	1242 ± 23	0.02

the created wetlands confirms the results of other studies that found low organic carbon content and nutrient availability likely limits the development of wetland creation projects (Bishel-Machung et al. 1996; Shaffer and Ernst 1999; Stolt et al. 2000). Mean bulk density was also significantly higher in mitigation sites (Table 1), which may reduce root growth and limit the accumulation of soil carbon. The addition of soil organic matter amendments, for example, from high organic matter compost or donor wetland soils could accelerate the development of high-quality soil, promoting the colonization of certain plant communities (Brown and Bedford 1997).

Vegetation

Plant species vary in their sensitivity to environmental stressors, making vegetation one of the most commonly used biotic assemblages for the assessment of a site's ecological condition, and as the basis to evaluate the temporal development of mitigation projects and set potential performance targets. Macrophytes respond predictably to environmental stressors such as hydrological changes, agricultural or urban land uses surrounding a site, high nutrient or sediment loads, or herbivory. The support of specific plant species provides an indication of its ability to support specific ecosystem functions and processes (Cronk and Fennessy, 2001; Fennessy et al. 2002). This is the basis for vegetation-based indicators like the Floristic Quality Assessment Index (FQAI) and the Vegetation Index of Biotic Integrity (VIBI; Mack and Micacchion 2000) that were used in this study (Fennessy et al. 2004). We also investigated plant community measures of species richness and aboveground biomass (Table 2).

The composition of the plant communities differed significantly. Mitigation sites had a higher relative abundance of tolerant (or generalist) species, fewer sensitive species, and fewer species of sedge genera such as *Carex* (Cyperaceae). FQAI scores were significantly lower ($p = 0.004$) in the mitigation (14.2) compared to the natural sites (21.6). This reflects the fact that generalist species tend to dominate in early successional or disturbed communities. The distribution of scores differed dramatically, for instance, 90% of the mitigation sites had FQAI scores of 15 or lower, while all of the natural sites scored above 15. VIBI scores ranged from 9 to 82 in the natural sites, confirming that they spanned the gradient of human disturbance. The range of scores for created wetlands was narrow, ranging from 16 to 50. This "compression"

Table 2 Summary of mean vegetation attributes for natural and mitigation wetlands. Values recoded are an average of the 9 natural sites and 10 mitigation sites (mean ± SE). P-values show results of a two-sample T-test to determine if means are significantly different (From Fennessy et al. 2004)

Vegetation attribute	Natural	Mitigation	p-value
Species richness	31.0 ± 4.4	25.6 ± 2.8	0.22
Vegetation index of biotic integrity	57.6 ± 8.1	27.2 ± 4.6	0.005
Floristic quality assessment index	21.6 ± 1.7	14.2 ± 0.7	0.004
Biomass production (g/m^2)	347 ± 35	209 ± 57	0.04

in scores is due, at least in part, to the high degree of similarity in plant community composition in the created sites where common, tolerant plant species dominated. While species composition varied, there was not a difference in species richness ($p = 0.22$).

Natural sites had significantly higher ($p = 0.04$) aboveground biomass (a measure of wetland primary productivity) with a mean of 347 g m^{-2} compared to 209 g m^{-2} in created sites. These biomass estimates are low compared to other wetland studies. For example, in a literature summary, Mitsch and Gosselink (2007) report biomass production ranging from 500 to 5500 g m^{-2}. Low productivity in the mitigation sites could be a result of environmental factors such as water depth or limited nutrient availability. Many of the mitigation wetlands had relatively deep and stable surface water levels, while many of the natural sites experienced a dry-down period in which very little or no surface water was present. Without a dry-down period during the growing season, seed germination is inhibited, potentially limiting both species diversity and biomass production (Cronk and Fennessy 2001).

Ecosystem Analysis

Experimental data from this case study shows that the mitigation wetlands differed from natural sites in terms of hydrology, soil characteristics, plant community composition, and the production of biomass. To synthesize some of these data and address the question of whether the mitigation sites are replacing the characteristics of lost wetlands, a cluster analysis was conducted to take an integrated view of these ecosystems by combining key measures of vegetation (FQAI scores) and percent soil C and N (Fig. 3). The analysis shows a clear division between natural and mitigation sites;

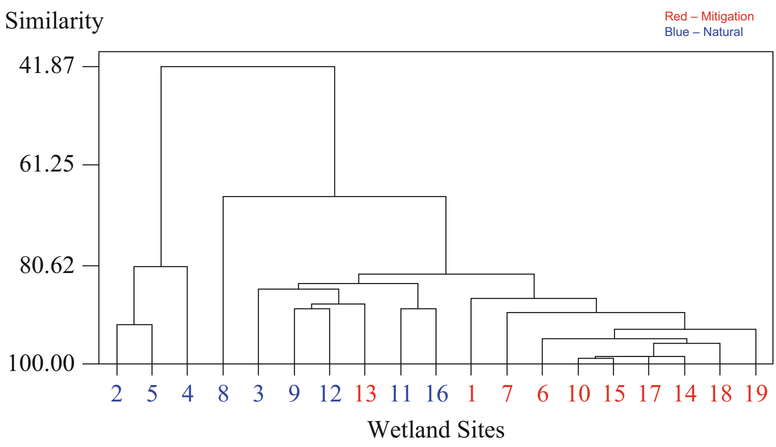

Fig. 3 Cluster analysis using the FQAI vegetation scores and soil characteristics (% total carbon and nitrogen). Natural wetlands are shown numbered in *blue* ($n = 9$) and created wetlands in *red* ($n = 10$)

mitigation wetlands differ in terms of individual components (e.g., soil, vegetation), as well as their overall ecosystem structure. Thus, the no net loss goal to replace the structure (and hence function) of wetlands has not been met by these mitigation sites.

Conclusions and Future Challenges

This case study, as well as the research of others, indicates that creating wetlands similar to natural sites (in both structure and function) takes more time than just the few years required for mitigation monitoring (typically five) and an understanding of the complexity of ecosystem components and their interactions. Based on these results, recommendations that might increase the likelihood of success in meeting the no net loss goal include:

1. Treatment of Soil During Construction: Hydric soils are the physical foundation for wetland ecosystems. They influence key ecosystem processes including microbially driven nutrient cycles, plant growth, water storage, and the composition of the biological communities (Stolt et al. 2000). Some mitigation project construction techniques negatively influence the composition and structure of wetland soils. For instance, created wetlands are often constructed by scraping off the top layer (A-horizon) of soil with heavy machinery. The A-horizon is typically where soil organic matter and plant nutrient concentrations are highest. Removing and compacting surface soils leaves them high in silts and clay materials, which can alter ecosystem development; for instance, Stolt et al. (2000) showed that excavating soil reduced soil nutrients, microrelief, and ultimately plant diversity. Many of the sites in this study were created by removing top soil and exposing the B-horizon, which was lacking in organic matter. We also found that soils did not improve with age. To overcome this problem, mitigation wetlands need more ecologically robust design and construction methods, for example, by requiring that replacement wetlands are true restoration projects (i.e., located where there are hydric soils present).
2. Wetland Hydrology: Hydrology is a key variable of wetland ecosystems, driving the development of wetland soils and the biotic communities. It plays a role in determining plant species composition, the spatial array of species, their productivity, and capacity for nutrient uptake (Cronk and Fennessy 2001). Groundwater exchange and movement through the root zone is an important component of natural systems. Recreating suitable wetland hydrology is essential to the development of mitigation wetlands.
3. Soil Nutrients: Where soil nutrient availability is low, steps should be taken to amend the soils during construction. Increasing organic matter (carbon) content has been shown to help vegetation establishment in mitigation projects. Stauffer and Brooks (1997) tested the application of leaf litter and soil organic matter to increase the performance of newly created wetlands. After 2 years, they found that leaf litter plots held an average of 8.2% organic matter, which more closely resembled the levels found in natural wetlands. While these results are

encouraging, more research needs to be done in this area. Studies investigating the effects of carbon and nitrogen amendments will aid in our understanding of the mechanisms behind C and N dynamics in mitigation wetlands.

4. The placement of a site within the landscape is a key consideration; we found the majority of the mitigation wetlands were atypical in terms of their hydrology or topographic position. A recommendation to address this is to use the HGM guidelines proposed, for example, by Brinson and Rheinhardt (1996) and Bedford (1996) when determining the location of a mitigation project.

The findings of this study have implications for the sustainability of our water resources, because the data help diagnose problems in mitigation wetland design which can then be used to set ecologically defensible performance targets. Mitigation project monitoring can be conducted using both previously developed biological indicators (e.g., FQAI, VIBI) and those based on the biogeochemical conditions (e.g., levels of soil organic carbon). The use of indicators to measure wetland ecological condition can improve monitoring of the project outcomes and help ensure their success in meeting the no net loss goal.

No Net Loss Case Study: Wetland Banking in Chicago (USA)

Morgan Robertson

Contents

Abstract

Compensation for permitted losses of wetlands and streams has been approved under the Clean Water Act in the USA since the late 1970s. A form of compensation known as wetland and stream banking was developed in the 1980s and has come to dominate compensation practices in the US. While most banks were initially developed by government agencies, the large majority of banks are now private and entrepreneurial. Although banking solves many of the problems identified with other forms of compensation, it does not do away with issues of temporal and spatial losses of wetland acreage and function. Data are presented from the use of compensation banking for wetland impacts permitted between 1994 and 2002 in the Chicago District of the US Army Corps of Engineers. While "no net loss" of wetland acreage is achieved by the end of the period, wetlands are not always present at bank sites by the time of the impact for which they compensate. Furthermore, whether "no net loss" is achieved depends on the scale at which the question is posed. Because of the spatial clustering of bank sites, banking results in losses being spread across many small watersheds while gains are concentrated in a few small watersheds.

Wetland Compensation and the Emergence of Wetland Banking

Compensation for permitted losses of wetlands and streams has been approved under the Clean Water Act in the USA since the late 1970s, but until the early 1990s, almost all types of compensation took the form of individual wetland restoration sites that were developed and managed by the party seeking the wetland permit. By 2000, a litany of problems with this kind of *permittee-responsible compensation* had been documented by researchers (see NRC 2001) and was familiar to Clean Water Act regulators at the US Army Corps of Engineers and the US Environmental Protection Agency (EPA). The most serious problems included the lack of arrangements for long-term stewardship (often these small sites, once built, were deeded to neighborhood associations or to public parks districts, without monies attached for management), the physical dispersal of these sites across large areas (Corps District staff lacked the time to visit each site and confirm its existence), and the vague or absent performance standards to which such sites would be held. Kevin Erwin's landmark study of all Florida compensation sites, published in 1991, documented that only 33% of such sites were ever even constructed and only 6% were meeting the (often unsatisfactory) performance standards specified in the permit for the impact. Clearly, this situation posed a major threat to meeting the mission of "no net loss of wetlands" (NNL) that had been a campaign slogan for President Bush in 1988, and was adopted by the Corps following the 1990 Water Resources Development Act.

The development of wetland banking addressed many of these key deficiencies with permittee-responsible compensation. Banking emerged slowly through the 1980s as large state or private organizations (usually Departments of Transportation or energy-sector firms) received permission to create large areas of advance compensation for planned future impacts. By 1990, the EPA and Corps had expressed their strong enthusiasm and support for the concept as a way of meeting the NNL requirement, although it was assumed that state or local governments would be the "bankers" of wetland credits. However, by the time of the 2001 National Research Council report that outlined the many failures and concerns with wetland compensation, banking was largely a private entrepreneurial activity, and the NRC singled banking out as a potentially important way to solve the problems of compensation. The advantages of banks in this respect are that they: (a) make it easy for regulators to visit and observe the compensation for many different permitted impacts with a single trip, (b) are sponsored by individuals or organizations who must pledge firm and well-funded arrangements for long-term stewardship, and (c) are usually held to detailed and ecologically based performance standards.

The Case of Chicago

In the Chicago District of the US Army Corps of Engineers (see Fig. 1), the first wetland banking credit was transacted in April of 1994. (The data presented here were first reported in Robertson (2006) and Robertson and Hayden (2008), and summarized in Robertson (2008).)

Between 1994 and 2002, 15 banks were approved, operated by 8 different private banking firms. 199 transactions were made at these banks in compensation for 241 individual impacts. A total of 309.321 credits were purchased to compensate

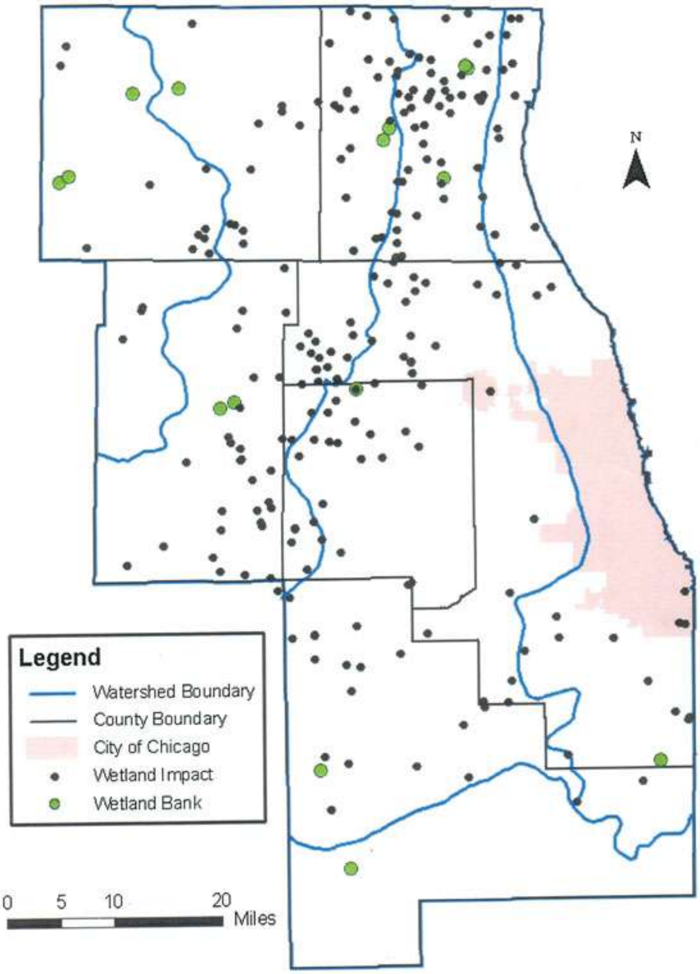

Fig. 1 The Chicago District of the US Army Corps of Engineers, showing the location of impact sites (*black*) that were compensated at wetland banks (*green*), and the watersheds within which the compensation was encouraged to stay (*blue*) (From Robertson 2006)

for 269.071 acres of impacts to wetlands; a credit was almost always defined as an acre of wetland, so this meets the basic definition of NNL: the overall replacement ratio during the time period was therefore 1.15:1. These transactions represented 31.8% of the compensation actions required by the Chicago Corps District and other regulatory agencies, but only provided compensation for 9.3% of the area impacted (Robertson 2008). Wetland bank credits were often used to compensate for smaller impacts, with an average purchase of 1.6 credits (where one credit usually equaled one acre of wetland). Did this practice assure "no net loss" of wetlands in the Chicago District? Yes and no.

While all of the credits sold at Chicago District banks eventually represented actual wetland restoration acreage, they did not always do so at the time of sale. Wetland banks in Chicago are allowed to sell a tranche of wetland credits after they have secured the site, have an approved restoration plan, have secured all necessary permits, and arranged for long-term funding of stewardship. They can sell 30% of their eventual credit total before the site has begun to be restored to a wetland condition. To require a site to meet all ecological performance standards prior to the first release of credits for sale would have forced private credit developers to wait 5 or more years before seeing any return on their investment, and would thus have ensured that only state agencies produced wetland credits. The arrangement for early sales meant that 60.3% of all transactions in Chicago occurred at banks that had not done any work on site development (see Fig. 2). Only 8.4% of transactions occurred at banks that had met all ecological performance standards. This undoubtedly represents an improvement over prior practices, as nearly all permittee-responsible compensation sites were built after the impact had been carried out and few were held to performance standards in any meaningful way. On the other hand, it represents an undeniable *temporal loss* of wetland area and functions.

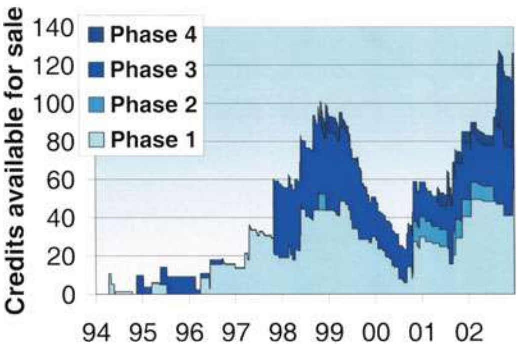

Fig. 2 The number of wetland bank credits available for sale in the Chicago District of the US Army Corps of Engineers, subdivided by the level of performance standard met: banks in Phase 1 had satisfied all administrative requirements but had not started development of the site; banks in Phase 2 had met hydrologic criteria; banks in Phase 3 had successfully implemented a vegetation planting plan; and banks in Phase 4 had met all performance criteria (Source: Robertson and Hayden 2008)

The Geography of Wetland Banking

Furthermore, there is always *geographic displacement* with wetland banking, because bank sites can be distant from the site of impact, while most nonbank compensation in the Chicago District was on the same property parcel as the impact. This creates the potential for other kinds of functional losses. The average distance between impact site and compensation site, where compensation was purchased at a bank, was 25.8 km (16.1 miles) between 1994 and 2002, but showed an increasing trend. Since compensation must be in the same Corps District as the impact, and the Chicago District is the smallest Corps District (most are much larger), this may be assumed to be a much smaller distance than the impact-compensation distance in other Districts.

Another aspect of geographic displacement involves the concentration of compensation at bank sites, resulting in a spatial clustering whereby some areas lose wetland area through banking and some gain it. The Chicago District of the Corps divided the District into five watersheds and required that compensation must occur in the same watershed as the impact (see Fig. 1). It was possible to compensate out of watershed, but the permittee would have to purchase twice as many credits: 79.7% of impacts were compensated within the defined watersheds, and each watershed (which were defined at the scale of 8-digit US Geological Survey codes) showed a clear net gain in wetland area as a result of banked compensation. However, when considered at other watershed scales, the pattern of loss and gain is different (see Fig. 3). At the scale of USGS 10-digit watersheds, 7 gained wetland acreage, 18 lost wetland acreage, and 15 were unaffected. Considering the even smaller USGS 12-digit watersheds, 10 gained wetland acreage, 63 lost wetland acreage, and 90 were unaffected. Wetland banking resulted in “no net loss” at the scale of

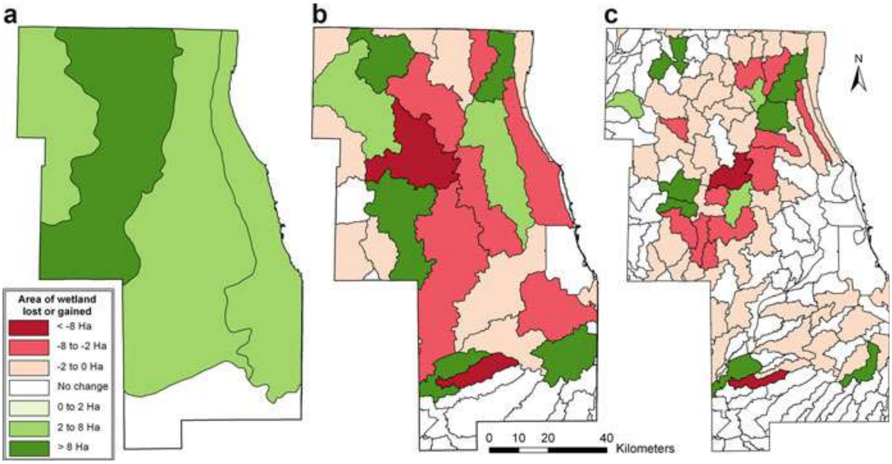

Fig. 3 Wetland acreage gain and loss in three scales of watershed in the Chicago District; (**a**) Corps-defined watersheds, (**b**) USGS 10-digit watershed classifications, (**c**) USGS 12-digit watershed classifications (From Robertson and Hayden 2008)

observation prioritized by regulators, but it created a clear geography of loss and gain when viewed at a finer geographic scale.

Challenges

Wetland banking in Chicago successfully addressed many of the obstacles to the implementation of a "no net loss" policy but did not fully address questions about temporal loss and the geography of loss and gain. It is clear that wetland banking involves the spatial and temporal displacement of wetlands; while these displacements may be more effectively monitored and managed than they are in other types of compensation, they are not well understood.

Other challenges (common to all types of compensation) include whether the assessments used to approve bank sites are appropriate to ensure that wetland functions are not lost, even as area increases. Many wetland assessment techniques measure structural features of hydrology and vegetation as imperfect proxies for the valued wetland functions that ensure a site's long-term viability.

Wetland banking has continued to grow rapidly as a compensation practice and by 2005 accounted for at least one third of all types of compensation. The release of the 2008 Corps and EPA "Compensation Rule" appears to have stimulated the wetland banking industry, and its preamble strongly highlighted the advantages of wetland banking in achieving no net loss. One consequence of this is the presence of a relatively vocal private-sector industry with unusual positions on environmental policy. The banking industry tends to lobby the US government to promote *increased* enforcement of the Clean Water Act (because increased enforcement drives increased business for them) and *higher* standards for compensation (because high standards prevent low-cost wetlands credits from flooding the market and sullying the reputation of their business). On the other hand, the continued viability of their business also relies on the continued issuance of permits to impact wetlands: permits which many environmentalists believe should be denied. The advantages and deficiencies observed in the Chicago case study remain with banking today.

Regulation of Activities for Wetland Conservation and Management: Overview

111

Mark Everard

Contents

Abstract

However strong the scientific and ethical case for the conservation of wetlands and their associated biodiversity and capacities to support human livelihoods, practical conservation and management depends upon a number of drivers. In this regard, "regulation" has a far broader meaning than purely the enactment of legislation. Indeed, statutory obligations may be poorly observed or poorly enforced, or may be practically unenforceable, in many territories, particularly in the developing world. The wider formal and informal policy environment, referred to collectively as societal levers, comprises statutory legislation, common/civil law, markets, market-based instruments, and both formal and informal protocols evolved as a fragmented policy environment of incentives and constraints influencing the freedoms of and rewards to resource owners and managers. Harmonisation of these societal levers with higher level sustainable aspirations is necessary to influence landowner or land manager decision-making at a local scale.

Introduction

However strong the scientific and ethical case for the conservation of wetlands and their associated biodiversity and capacities to support human livelihoods, practical conservation and management depends upon a number of drivers. In this regard, "regulation" has a far broader meaning than purely the enactment of legislation. Indeed, statutory obligations may be poorly observed or poorly enforced, or may be practically unenforceable, in many territories, particularly in the developing world.

It is for this reason that this overview takes a broader view of "regulation" to encompass the diversity of "societal levers" identified by Everard et al. (2014) to connect higher level sustainable aspirations with practical influences on landowner or land manager decision-making at a local scale. These "societal levers" include statutory legislation, common/civil law, markets, market-based instruments, and both formal and informal protocols, which have evolved as a fragmented policy environment of incentives and constraints influencing the freedoms of and rewards to resource owners and managers.

The following overview considers these broad categories of "societal levers" in turn. Far more detail on individual "levers" is provided in other chapters in this Wetland Book.

Statutory Legislation

Statutory legislation and associated regulatory obligations represent formalized "rules" agreed by society. Some protect the rights of resource owners, but many act to constrain actions that infringe the freedoms of other sectors of society. These agreements may be supranational (such as EU Directives), national (Acts of Parliament and subsidiary Regulations), or local (for example, by-laws).

Some statutory protections have yielded significant successes for ecosystems and selected services, for example, through various wildlife, water resource, air quality, and landscape protection legislation. Specific pieces of legislation directly affecting wetlands in a European context include the EU Habitats Directive, Birds Directive and, where wetlands are explicitly recognized as constituting at least part of "Water Bodies," the Water Framework Directive. (For more details see ▶ Chap. 59, "Transnational and Regional Legal Frameworks.")

However, the primary focus of this overview is on regulation of activities affecting wetland conservation and management, rather than those centered on the wetlands themselves. As wetlands are part of mosaic natural and human landscapes, regulation of development activities – urban, infrastructure, industrial, and land use – have a significant potential to affect wetlands both directly and more remotely. These potential impacts need therefore to be addressed in proposals for development before impacts occur, enabling their avoidance, reduction, or mitigation (see ▶ Chap. 115, "Avoid-Mitigate-Compensate Sequence: Wetland Conservation").

For this purpose, and associated with various strands of legislation, various regulatory tools and obligations are imposed on development proponents. (Examples include ▶ Chaps. 112, "Environmental Impact Assessments," ▶ 113, "Strategic Environmental Assessments," ▶ 114, "Permit Schemes," ▶ 117, "Compensation in Wetlands," ▶ 118, "Mitigation Banking for Wetlands," ▶ 130, "In-Lieu Fees in Wetlands," ▶ 119, "Enforcement: Wetlands," and ▶ 135, "Property Rights.")

Common Law

English common law is founded on the protection of rights, evolving since Roman times through a less formalized body of case law to uphold the rights of individuals or communities potentially infringed by the actions of others. The system of English common law is replicated in many countries across the world, although it cannot be assumed to operate identically in all jurisdictions. For example, Scotland has a civil law, rather than a common law. Nevertheless, the broad principle of evolving case law based on judgments about the rights of different people lies at its core.

Case law relating to rights to air, water, soil, and enjoyment of a natural environment of undiminished quality as well as sporting or access rights demonstrates common law protection progressively extending to some of what we now term ecosystem services, including those provided by wetlands, such as protection of the quality and enjoyment of recreational fisheries (Carty and Payne 1998). Representing as they do the multiple ways in which different sectors of society benefit from ecosystems, ecosystem services represent a wider framework of public rights, many of them historically omitted from management considerations, to which common law protection may be extended by case law (Everard and Appleby 2008; Everard et al. 2012).

As such, beneficiaries of the ecosystem services provided by wetlands – be they provisioning, regulatory, cultural, and/or supporting services – may have a case in law to seek an injunction on activities likely to damage a wetland resource and its beneficial services or else to sue for compensation for any damages that may have occurred. Sporting rights that can be tied down to damage to "property" have been the source of rich case law over centuries (Carty and Payne 1998). English manorial court records from the postmedieval period also provide a rich source of case law relating to resource conflicts, particularly with respect to water with the spread of the once-dominant water meadow system in the catchments of Wessex rivers which spurred conflicts between water meadow operators, mills, navigation and fishery interests, and other users of river flows (Bettey 1999). Property rights associated with wetlands can thus constitute levers for their protection as well as for their exploitation (see ► Chap. 135, "Property Rights").

Markets

Markets exert a significant, indeed sometimes an overwhelmingly dominant, influence over choices about the management of natural resources. Markets most commonly favor provisioning services but generally fail to recognize that their production is heavily dependent on the underpinning support of a wide range of additional ecosystem services (Power 2010).

Some market failures damaging water, wetland, and other environmental resources and associated human wellbeing are beginning to be addressed, for example, the recent evolution of carbon markets and the institution in the UK of an Aggregates Levy on mined substances. However, most ecosystem services remain external to current markets, and their value to society is therefore inadequately incorporated into policy and business calculations. Agriculture has been the foremost pressure leading to the degradation of wetlands habitat worldwide, largely driven by consumer pressure (Millennium Ecosystem Assessment 2005) reinforced by governments through a food security agenda (Everard 2011) as well as favoring short-term economic growth over long-term consequences. Securing adequate food and maintaining economic growth for a growing population are pressing and legitimate priorities for governments and individuals, but exploitation of ecosystems at the expense of longer-term and wider societal needs not only conflicts with stated commitments to sustainable development but also represents short-termism, a substantial market failure, and the consequent creation of multiple vulnerabilities.

Were markets to evolve to recognize more of the multiple values provided by wetland and other natural systems, these foundational resources would be greater valued and protected. Examples of this occurring include the shift in flood control globally from a paradigm of local "flood defense" of assets at risk to a more systemic consideration of flood risk management by considering flows of water through whole connected catchment wetland systems and increasing use of "natural flood management" techniques (Everard et al. 2009).

Market-Based Instruments

Various market-based instruments have also been developed to promote aspects of societal wellbeing supported by environmental resources and processes. These are commonly related to statutory agreements, including both inducements (such as agri-environment subsidies) and levies to constrain exploitation or generate environmentally compensating projects (such as the UK Landfill Tax and Aggregates Levy).

Successive iterations of the EU Common Agricultural Policy (CAP) represent market interventions that have shifted from a primary focus on output support, from a time when food scarcity drove policy, through to broader social and environmental goals. The EU CAP has had a dominant influence on management of much of the European rural landscape and hence on the balance of ecosystem services that are either favored or eroded. Given the dominant influence of agriculture on the global wetland resource to date (Millennium Ecosystem Assessment 2005), future agriculture and food policy and internalization of their potential harm to wetlands and the human interests that stem from them will inevitably have profound implications for the balance of ecosystem service production.

Voluntary payment mechanisms such as "payments for ecosystem services" (PES) schemes can also specifically secure the supply of valued ecosystem services wherein payments from "consumers," or "buyers," of ecosystem services are accepted by those "producing" those services (Wunder 2005). A water utility, for example, benefitting from higher quality river water requiring less "clean up" costs, may pay farmers, typically via an intermediary body, for undertaking water-sensitive farming practices beyond those required by statute (Smith et al. 2013). The OECD estimated that there were already more than 300 PES or "PES-like" schemes in operation globally by 2010, addressing a diversity of services ranging from water supply to carbon sequestration, conservation of biodiversity, amenity and recreational opportunity, and ranging from global to local scales (OECD 2010). Interest in PES has since increased substantially, Schomers and Matzdorf (2013) identifying 457 published peer-reviewed papers on PES addressing a small subset of many more schemes around the world. (See Economic Incentives to Conserve/Manage Wetlands [Non-regulatory]).

Formal and Informal Protocols

In addition to legal and market mechanisms, a range of protocols to safeguard selected desirable services has been established. Among the wide variety of protocols influencing societal choices, the 1971 Convention on Wetlands (the "Ramsar Convention": www.ramsar.org) represents a pioneer of the Ecosystem Approach, explicitly acknowledging the global resource of wetland ecosystems not merely as ecologically important but also as central to the livelihoods and future socioeconomic prospects of people, therefore requiring "Wise Use" (since acknowledged as synonymous with "sustainable development" and mirroring the Ecosystem Approach).

Other relevant international protocols affecting management activities that may impinge upon wetlands include the United Nations Framework Convention on Climate Change (UNFCCC: www.unfccc.int) and Convention on Trade in Endangered Species of Wild Fauna and Flora (CITES: www.cites.org).

At national scale, the target to achieve 25% forest cover in the Scotland Land Use Strategy (Scottish Government 2011) is a national-scale aspiration that is not statutory and is at present supported only by a fragmented set of national economic incentives delivered under the Rural Development Program (Everard et al. 2014). Policies established by major landowning or otherwise influential organizations, such as the National Trust in England, in Wales and in Scotland, the Royal Society for the Protection of Birds (RSPB) or the National Farmers' Union, may also be regarded as forms of nonstatutory but nevertheless significant protocols establishing governing policies influencing the management of wetlands and other natural resources and the production of ecosystem services.

Boundaries Between "Societal Levers"

The boundaries between statutory, common law, market and market-based, and both formal and informal protocol levers are not fixed, with one measure potentially transforming into another. For example, issues of concern addressed by common case law may evolve into statutory legislation as in the case of many contemporary laws relating to the air and atmosphere as well as water systems (Everard et al. 2012), which may in turn instigate market preferences, inducements, or disincentives.

Conclusions and Challenges

One of the strengths of the often organically evolving nexus of "societal levers" influencing resource owners and managers is that it produces the heterogeneous mosaic landscapes familiar around the world, reflecting both natural conditions and landowner aspirations. Collectively, these societal levers safeguard or otherwise influence some socially valuable ecosystem services, including those produced by and affecting wetlands.

However, Everard et al. (2014) also conclude that the present policy environment is neither sufficient nor sufficiently integrated to achieve coherence between the choices of resource owners and wider societal aspirations for ecosystem service provision. The fragmented manner and service-by-service basis on which these various levers have evolved, often as a reaction to localized and acute issues of concern, does not automatically moderate the freedom of choice of landowners, often in localized geographical contexts, to favor the production of service outcomes of optimal benefit to all in society at catchment and other landscape scales (Everard et al. 2014). Indeed, the plethora of competing incentives, from CAP to habitat-enhancing support, may make it difficult for landowners to identify what is best for the common good, however defined, and to allow them to choose practices serving this common good while at the same time reaping individual benefits. The net consequence is that the integrity and vitality of wetland systems that may be affected adversely both directly and indirectly may not be seen as a priority.

Further evolution of "societal levers" – the diversity of statutory and informal influences on practical management decision-making – is therefore a necessity to bring about greater coherence from high-level (international and national) down to local-scale protection of wetland systems and their associated ecosystem services.

Environmental Impact Assessments 112

Mark Everard

Contents

Abstract

Environmental impact assessment (EIA) is a formal process used to predict environmental consequences, which may be positive or negative, of a plan, policy, program, or project prior to approval. The International Association for Impact Assessment (IAIA) defines an environmental impact assessment as "*. . .the process of identifying, predicting, evaluating and mitigating the biophysical, social, and other relevant effects of development proposals prior to major decisions being taken and commitments made.*" EIAs should contain proposals for scheme design or operation to reduce these impacts to acceptable levels or to address different technical solutions. "Acceptable levels" is a contested and political concept, though the purpose of an EIA is to inform better decision-making by bringing wider environmental concerns into consideration alongside economic, social, and political concerns.

Introduction

Environmental impact assessment (EIA) is a formal process used to predict environmental consequences, which may be positive or negative, of a plan, policy, programme, or project prior to approval. The International Association for Impact Assessment (IAIA) defines an environmental impact assessment as "*. . .the process of identifying, predicting, evaluating and mitigating the biophysical, social, and other relevant effects of development proposals prior to major decisions being taken and commitments made*" (International Association for Impact Assessment 1999).

EIAs should contain proposals for scheme design or operation to reduce these impacts to acceptable levels or to address different technical solutions. Clearly, "acceptable levels" is a contested and political concept, though the purpose of an EIA is to inform better decision-making by bringing wider environmental concerns into consideration alongside economic, social, and political concerns. Each EIA is unique, not requiring adherence to a predetermined environmental outcome but rather requiring decision-makers to take account of environmental values in their decisions. This then, at least in theory, drives a more sustainable and transparent process of development.

The Origins and Development of EIAs

Development of the EIA process commenced in the 1960s, spurred on by growing environmental awareness. In the USA, environmental impact assessments obtained formal status with enactment of the National Environmental Policy Act (NEPA) in 1969 (Department of Environment n.d.; Clark and Canter 1997). EIAs are effectively a more streamlined version of the more detailed environmental impact statements (EISs), also brought into law in the USA under the NEPA, to provide more detail about actions "*. . .significantly affecting the quality of the human environment.*" EIAs are more commonly referred to in the USA as environmental assessment (EA), a public document comprising an environmental analysis prepared to determine whether a federal action would significantly affect the environment. If the ES finds that it might have significant impact, a more detailed environmental impact statement (EIS) is required. If not, a *Finding of No Significant Impact* (FONSI) is issued. This process is administered in the USA by the Council on Environmental Quality (CEQ).

EIAs have since been increasingly deployed throughout the world as a rapid means to assess the scale of potential impacts of schemes before development occurs. For example, in Australia, EIA procedures were introduced at a state level prior to that of the Commonwealth (Federal). The pioneering Australian state was New South Wales, in which the State Pollution Control Commission issued EIA guidelines in 1974. This was followed by the passing in 1974 at Commonwealth (Federal) level of the Environment Protection (Impact of Proposals) Act, superseded by the Environment Protection and Biodiversity Conservation Act 1999 (EPBC), each promoting the EIA process.

In Canada, the EIA process entered the mainstream of environmental management through common law challenges, ultimately formalized in the Canadian Environmental Assessment Act 2012 which describes EA as a planning tool to identify, understand, assess, and mitigate, where possible, the environmental effects of a project.

In China, the Environmental Impact Assessment Law (EIA Law) requires that an environmental impact assessment be completed prior to project construction. However, the only penalty in the event that a developer ignores this requirement before implementing a project without first submitting an environmental impact statement is that the Environmental Protection Bureau (EPB) may require the developer to produce a retrospective environmental assessment. Only if the developer fails to do this within a designated time is the EPB then authorized to fine the developer up to a relatively low capped amount. This lack of stringent enforcement mechanisms results in a significant proportion of projects disregarding the EIA requirement (Wang 2007).

In the EU, the Environmental Impact Assessment (EIA) Directive has been in force for 25 years and is currently being revised (EU 2014). Other nations and jurisdictions requiring EIAs include Egypt, Hong Kong, India, Malaysia, Nepal, New Zealand, the Russian Federation, and Sri Lanka.

Application of EIA

A wide range of EIA methods is available across these territories to implement the EIA process to a range of applications. On project completion, an audit is generally required to evaluate the accuracy of the EIA by comparing actual to predicted impacts, including both scientific assessment of predictions and errors as well as the success of mitigation measures.

However, the EIA process is not without its critics. For example, EIA is often regarded as a decision-aiding tool rather than a decision-making tool (Jay et al. 2007). Conversely, EIAs are often seen by development proponents as being costly and hampering development. There is also generally a lack of clear definition of the spatial bounding of impacts, resulting in almost all EIAs addressing only direct and immediate on-site effects rather than systemic impacts (Lenzen 2003).

EIA and Wetlands

The Ramsar Convention Secretariat produced a Handbook on *Impact assessment* (Ramsar Convention Secretariat 2010) in response to recognition that the concepts of environmental impact assessment (EIA) and strategic environmental assessment (SEA) were increasingly seen as necessary components of international environmental policy and law. Despite a clear role for impact assessment being spelt out in the texts of a range of conventions, detailed implications for wetlands within both EIA and SEA were lacking despite their evident importance.

Consequently, the Convention on Biological Diversity's *voluntary guidelines on biodiversity-inclusive environmental impact assessment* and also the CBD's *guidance on biodiversity-inclusive strategic environmental assessment* were adopted by the Ramsar Commission in 2008. This reaffirmed the role of impact assessment (environmental, strategic, and social) and economic valuation as key tools for assisting the contracting parties in their efforts to achieve the objectives of the convention, calling upon contracting parties to the Ramsar Convention "*...to reinforce and strengthen their efforts to ensure that any projects, plans, programmes and policies with the potential to alter the ecological character of wetlands in the Ramsar List, or impact negatively on other wetlands within their territories, are subjected to rigorous impact assessment procedures and to formalise such procedures under policy, legal, institutional and organizational arrangements.*" The ensuing guidelines for incorporating biodiversity-related issues into EIA and SEA are essentially voluntary in nature.

The CBD voluntary guidelines on biodiversity-inclusive environmental impact assessment, outlined in the Ramsar Convention Secretariat (2010) handbook, specify stages in the EIA process and how to address biodiversity issues at each of them. These are:

- *Screening* determines which projects or developments require a full or partial impact assessment study. Screening criteria have to include biodiversity measures if proposals with potentially significant impacts on biodiversity are to be screened out. However, legal requirements for EIA may not guarantee that biodiversity will be taken into account, so consideration should therefore be given to incorporating biodiversity criteria into existing, or developing new, screening criteria. The outcome of the screening process is a *screening decision*.
- *Scoping* to identify which potential impacts are relevant to assess (based on legislative requirements, international conventions, expert knowledge, and public involvement), to identify alternative solutions that avoid, mitigate, or compensate adverse impacts on biodiversity (including the option of not proceeding with the development, finding alternative designs or sites which avoid the impacts, incorporating safeguards in the design of the project, or providing compensation for adverse impacts), and finally to derive terms of reference for the impact assessment.
- *Assessment and evaluation of impacts and development of alternatives*, to predict and identify the likely environmental impacts of a proposed project or development, including the detailed elaboration of alternatives.
- *Reporting*: the environmental impact statement (EIS) or EIA report, including an environmental management plan (EMP) and a nontechnical summary for the general audience.
- *Review* of the environmental impact statement, based on the terms of reference (scoping) and public (including authority) participation.
- *Decision-making* on whether to approve the project or not and under what conditions.

- *Monitoring*, *compliance*, *enforcement*, *and environmental auditing*, comprising monitoring of whether the predicted impacts and proposed mitigation measures occur as defined in the EMP, verification of compliance by the proponent with the EMP, and post-project auditing to ensure that unpredicted impacts or failed mitigation measures are identified and addressed in a timely fashion.

Pertinent questions from a biodiversity perspective should be raised at all stages of EIA development. These should include whether the intended activity may:

- Affect the biophysical environment directly or indirectly in such a manner or cause such biological changes that it will increase risks of extinction of genotypes, cultivars, varieties, populations of species, or the chance of loss of habitats or ecosystems
- Surpass the maximum sustainable yield, the carrying capacity of a habitat/ecosystem, or the maximum allowable disturbance level of a resource, population, or ecosystem, taking into account the full spectrum of values of that it provides
- Result in changes to the access to and/or rights over biological resources

To facilitate the development of screening criteria, the Ramsar Convention Secretariat (2010) handbook highlights the importance of exploring biodiversity at the levels of ecosystem diversity, species diversity, and genetic diversity.

As developments can affect both the structure of wetlands and the ways in which they function, incorporation of wetland impacts in EIA processes is very important. All likely impacts arising from the type and scale of development will impact need to be assessing, whether within the wetland or in the catchment area surrounding it. Examples of the kinds of wider consideration of impacts to be considered in an EIA include:

- Does the physical structure of the development affect the wetland directly, for example by drainage or permanent alteration, or indirectly by impinging on the wetland or changing the hydrology of the catchment that serves it?
- Might fertilisers, other nutrients, or pollutants in run-off from land cause ecological change in the wetland?
- Can management inputs, including for example pesticides or herbicides, run into the wetland with likely negative impacts for flora, fauna, and water quality?
- Can disturbance from increased human activity in or close to the wetland affect the ecosystem and its functioning?

The EIA should therefore:

- Delineate the wetland.
- Assess wetland biodiversity and its value and vulnerabilities.
- Address the broader potential direct and indirect impacts of the proposed development on the wetland, together with any requisite mitigation measures.

- Consider cumulative impact on the broader catchment or the effects on the entire wetland environment.
- Identify buffer areas around wetlands to protect them from impacts from the proposed development.

Strategic Environmental Assessments

113

Mark Everard

Contents

Abstract

Strategic impact assessment (SEA) is a systematic decision support process, aimed generally at the programmatic level rather than at project of individual scheme level. (The *Environmental impact assessment* process is generally applied at more localized scheme level.) The purpose of SEA is to ensure that environmental and possibly other sustainability aspects are considered effectively in policy, plan, and program making.

Keywords

localized scheme level.). The purpose of SEA is to ensure that environmental and possibly other sustainability aspects are considered effectively in policy, plan, and program making.

Background to SEA

Although the Environmental Impact Assessment (EIA) process assesses scheme level proposals for development, for example as specified in the European Union EIA Directive (85/337/EEC) currently under revision (EU 2014), EIA only applies to certain projects and specific effects at the local level. EIA alone is therefore deficient as deficient. This is due to the fact that many environmentally damaging decisions will have already been made at a more strategic level. As one example, an EIA on a local road scheme may overlook the fact that new transport infrastructure may generate an increased demand for travel. Consequently, the concept of Strategic Impact Assessment (SEA) originated in regional development and land use planning decision-making in the developed world.

The *U.S. Housing and Urban Development Department* published in 1981 an *Area-wide Impact Assessment Guidebook* which contained many of the principles now enshrined in the SEA process. Meanwhile, in Europe, the UNECE (1991) *Convention on Environmental Impact Assessment in a Transboundary Context* (the Espoo Convention) established foundations for the introduction of SEA in 1991. Subsequently, the European SEA Directive 2001/42/EC (EU 2001) required that all Member States of the European Union should have ratified and transposed the Directive into national legislation by 2004. SEA has subsequently been implemented in EU Member States since that time.

SEA is also applied in other countries around the world. For example, in New Zealand, SEA constitutes part of an integrated planning and assessment process under the Resource Management Act, which has the principal objective of sustainable management. The OECD (Organization for Economic Cooperation and Development) is developing guidance on SEA, which may result in its more widespread and consistent adoption.

How SEA Works

Fischer (2007) describes SEA as a process of:

- A structured, rigorous, participative, open, and transparent environmental impact assessment (EIA)-based process, applied particularly to plans and programs, prepared by public planning authorities and at times private bodies
- A participative, open and transparent, possibly non-EIA-based process, applied in a more flexible manner to policies, prepared by public planning authorities and at times private bodies

- A flexible non-EIA-based process applied to legislative proposals and other policies, plans, and programs (PPP) in political/cabinet decision-making

Effective SEA operates as a tiered decision framework. Under the EU SEA Directive, SEA is based on the following phases:

- Screening: investigation of whether the plan or program falls under the SEA legislation
- Scoping: defining the boundaries of investigation, assessment, and assumptions required
- Documentation of the state of the environment: constituting a baseline on which to base judgments
- Determination of the likely environmental impacts of development usually in terms of Direction of Change rather than firm figures
- Informing and consulting the public
- Influencing "decision taking" based on the assessment
- Monitoring of the effects of plans and programs after their implementation

The EU SEA Directive also includes other impacts besides environmental considerations, such as material assets and archaeological sites. In most western European states, this has been broadened further to include economic and social aspects of sustainability.

SEA and Wetlands

The Ramsar Convention Secretariat produced a Handbook on *Impact assessment* (Ramsar Convention Secretariat 2010) in response to recognition that the concepts of environmental impact assessment (EIA) and strategic environmental assessment (SEA) were increasingly seen as necessary components of international environmental policy and law. Despite a clear role for impact assessment being spelt out in the texts of a range of conventions, detailed implications for wetlands within both EIA and SEA were lacking despite their evident importance.

Consequently, the Convention on Biological Diversity's *voluntary guidelines on biodiversity-inclusive environmental impact assessment* and also the CBD's *guidance on biodiversity-inclusive strategic environmental assessment* were adopted by the Ramsar Commission (2008). This reaffirmed the role of impact assessment (environmental, strategic, and social) and economic valuation as key tools for assisting the Contracting Parties in their efforts to achieve the objectives of the Convention, calling upon Contracting Parties to the Ramsar Convention "…to reinforce and strengthen their efforts to ensure that any projects, plans, programmes and policies with the potential to alter the ecological character of wetlands in the Ramsar List, or impact negatively on other wetlands within their territories, are subjected to rigorous impact assessment procedures and to formalise such procedures under policy, legal, institutional and organizational arrangements." The ensuing guidelines for incorporating biodiversity-related issues into EIA and SEA are essentially voluntary in nature.

The CBD voluntary guidelines on biodiversity-inclusive environmental impact assessment, outlined in the Ramsar Convention Secretariat (2010) handbook, specify stages in both SEA and EIA processes and how to address biodiversity issues at each of them. These are:

- *Screening* determines which projects or developments require a full or partial impact assessment study. Screening criteria have to include biodiversity measures if proposals with potentially significant impacts on biodiversity are to be screened out. However, legal requirements for EIA may not guarantee that biodiversity will be taken into account, so consideration should therefore be given to incorporating biodiversity criteria into existing, or developing new, screening criteria. The outcome of the screening process is a *screening decision*.
- *Scoping* to identify which potential impacts are relevant to assess (based on legislative requirements, international conventions, expert knowledge, and public involvement); to identify alternative solutions that avoid, mitigate, or compensate adverse impacts on biodiversity (including the option of not proceeding with the development, finding alternative designs or sites which avoid the impacts, incorporating safeguards in the design of the project, or providing compensation for adverse impacts); and finally to derive terms of reference for the impact assessment.
- *Assessment and evaluation of impacts and development of alternatives*, to predict and identify the likely environmental impacts of a proposed project or development, including the detailed elaboration of alternatives.
- *Reporting*: the environmental impact statement (EIS) or EIA report, including an environmental management plan (EMP), and a nontechnical summary for the general audience.
- *Review* of the environmental impact statement, based on the terms of reference (scoping) and public (including authority) participation.
- *Decision-making* on whether to approve the project or not and under what conditions.
- *Monitoring*, *compliance*, *enforcement*, *and environmental auditing*, comprising monitoring of whether the predicted impacts and proposed mitigation measures occur as defined in the EMP, verification of compliance by the proponent with the EMP, and postproject auditing to ensure that unpredicted impacts or failed mitigation measures are identified and addressed in a timely fashion.

Pertinent questions from a biodiversity perspective should be raised at all stages of SEA development. These should include whether the intended activity may:

- Affect the biophysical environment directly or indirectly in such a manner or cause such biological changes that it will increase risks of extinction of genotypes, cultivars, varieties, populations of species, or the chance of loss of habitats or ecosystems

- Surpass the maximum sustainable yield, the carrying capacity of a habitat/ecosystem, or the maximum allowable disturbance level of a resource, population, or ecosystem, taking into account the full spectrum of values that it provides
- Result in changes to access to, and/or rights over, biological resources

To facilitate the development of screening criteria, the Ramsar Convention Secretariat (2010) handbook highlights the importance of exploring biodiversity at the levels of ecosystem diversity, species diversity, and genetic diversity.

Abstract

Despite international recognition through various treaties, wetlands remain one of the most undervalued and least understood of all global natural resources. One reason for this is the inevitable conflict between wetland preservation measures and the landowner's freedom of choice in developing property. Permit-based regulatory systems that are designed to protect wetlands generally require permission from the government before conducting activities such as filling or otherwise altering the wetland. Permit-based legal mechanisms throughout the world designed to facilitate wetland management and the wise use of wetlands are reviewed. This includes an overview of international law calling for regulation and conservation of wetlands, then focuses on the United States' permit program and regulatory programs in several other countries. Opportunities for market-based incentives through mitigation banking are considered.

Introduction

Despite international recognition through various treaties, wetlands remain one of the most undervalued and least understood of all global natural resources (Fiore 1993). In the United States, 82% of the nation's assessed wetlands acreage are impaired in at least one respect (Adler 2013). One reason is the inevitable conflict between wetland preservation measures and the landowner's freedom of choice in developing property. Permit-based regulatory systems that are designed to protect wetlands generally require permission from the government before conducting activities such as filling or otherwise altering the wetland.

This entry reviews the current permit-based legal mechanisms throughout the world designed to facilitate wetland management and the wise use of wetlands. The entry first explores international law calling for regulation and conservation of wetlands. It then outlines the United States' permit program and highlights regulatory programs in several other countries. Finally, the entry identifies opportunities for market-based incentives through mitigation banking.

International Laws

Numerous international laws seek to protect wetlands directly or indirectly as habitat for imperiled species. For example, the Convention on Wetlands of International Importance Especially as Waterfowl Habitat, known as the Ramsar Convention, creates an international legal framework for the protection and wise use of wetlands (Kim 2011). Each party to the Ramsar Convention must designate at least one site to include on the List of Wetlands of International Importance and promote conservation of listed wetlands. Even broader than the Ramsar Convention, the Convention on Biological Diversity takes an ecosystem perspective to encourage the conservation of biological diversity and sustainable use (Gardner 2003). The Convention on the Conservation of Migratory Species of Wild Animals, known as the Bonn Convention, not only focuses on conserving migratory species but also protects wetland function or value where the wetlands provide habitat for migratory species (Gardner 2003). Canada, the United States, and Mexico are parties to the North American Waterfowl Management Plan, which also promotes wetland conservation and restoration due to its focus on protecting wetland-dependent species (Gardner 2003). Despite these agreements, a few contain binding legal obligations and thus the extent of implementation varies considerably.

Domestic Permit Schemes

Many countries, including leading wetland conservation countries, do not have legislation or policies that exist specifically to protect wetland (Kim 2011). This includes Denmark, Germany, and the Netherlands. The United States applies a policy goal of "no net loss" of wetland functions and values. Countries with a similar "no net loss" policy include Canada, the European Union, and Trinidad and Tobago (Gardner 2003). Countries like Australia, Colombia, Costa Rica, Ghana, New Zealand, and Uganda focus instead on wetlands restoration (Gardner 2003).

United States

The United States has one of the most extensive permit schemes, regulating both public and privately owned wetlands (Gardner 2003). As development of land in the United States continues, less desirable land has become the focus of construction projects (Braddock 2007). It is the official US policy to allow wetlands to be filled pursuant to the conditions of a dredge and fill permit (Adler 2013).

Section 404 of the Clean Water Act is the most significant piece of federal legislation that directly regulates activities affecting wetlands (Fiore 1993). Pursuant to its authority under the Commerce Clause of the United States Constitution, Congress enacted the Clean Water Act with a goal "to restore and maintain the chemical, physical, and biological integrity of waters of the United States" (33 U.S.C. § 1251 et seq.)

The Clean Water Act prohibits the discharge of a pollutant from a point source to waters of the United States, unless pursuant to a permit. Most activity that places solid matter in a wetland will require a dredge and fill permit, also known as a "section 404" permit (Braddock 2007). Each element is necessary to trigger the permit requirement: a discharge, a pollutant, a point source, and a water of the United States. Not surprisingly, many of these elements have been the subject of controversy and litigation (Braddock 2007). Defining the term "waters of the United States" has been especially troublesome (Adler 2013). Notwithstanding the triggering elements, certain activities are exempt, including agriculture and silviculture activities (Braddock 2007).

The United States Army Corps of Engineers is the lead agency under section 404, and may authorize dredge and fill activities pursuant to a General Permit, Nationwide Permit, or individual permit (Braddock 2007). The Environmental Protection Agency retains oversight by writing the guidelines for issuance of a section 404 permit and retaining the authority to veto any permit issued by the Corps (Adler 2013). The Corps may issue General and Nationwide Permits on a state, regional, or nationwide basis for activities that are similar in nature and impact, and cause only minimal cumulative adverse effects. General and Nationwide Permits provide flexibility so that many routine activities can occur with little delay or paperwork (Strand and Rothschild 2009). Critics have raised concerns about the total wetland loss attributable this streamlined permit process (Strand and Rothschild 2009).

Individual permits provide a more comprehensive review of a specific proposal to fill or dredge a wetland (Strand and Rothschild 2009). The Corps may issue an individual section 404 permit if it determines, pursuant to US Environmental Protection Agency's (EPA's) guidelines, that the proposed activity is the least environmentally damaging practicable alternative and the discharge will not have significant adverse environmental consequences. Other federal statutes may also apply to the activity, including the Coastal Zone Management Act, the Endangered Species Act, and the National Environmental Policy Act.

Noncompliance can result in civil and criminal liability (Braddock 2007). The Corps, EPA, or the United States Department of Justice may enforce the Clean Water Act (Braddock 2007). Citizens may also enforce unpermitted discharges. Judicial review is available for permit denials or penalties assessed (Fowler 2003).

States play an important role in the permit process. States may displace the Corps' authority if the state's permit program meets statutory requirements, although only Michigan and New Jersey have done so (Fiore 1993). The Clean Water Act also allows states to maintain concurrent jurisdiction under their own state laws. Finally, the Corps may not issue a section 404 permit if the affected state denies water quality certification (Fiore 1993).

Other Permit Schemes

Permit schemes in other countries tend to be narrower in application. For example, the European Union requires participating countries protect of ecosystems, including wetlands, but only at designated Natura 2000 sites (Gardner 2003).

Federal regulation in Canada typically occurs as a function of the protections provided by other statutes protecting wildlife (Fiore 1993). For many jurisdictions, wetland policy is absent or in the early stages of development (Clare et al. 2011). One exception is Alberta, Canada, where the wetland policy resembles that of the United States (Clare et al. 2011). The 1999 Water Act requires approval for any activity that may cause an effect on the aquatic environment (Clare et al. 2011). Limiting this approach is the purpose of the act, which requires conservation goals to be balanced with Alberta's need for economic growth and prosperity. Alberta's regulations also do not require an alternatives analysis or a formal process for identifying the basic purpose of a project (Clare et al. 2011).

In the Republic of Korea, the Public Waters Reclamation Act grants private property rights in reclaimed lands to those with a reclamation permit (Kim 2011). Reclamation permits are issued to accommodate and grant consent to those who seek to use public waters or drain or reclaim privately owned public waters (Kim 2011). Recent amendments to the act require reclamation activities be environmentally friendly and disclose any environmental impacts on the site (Kim 2011). Yet environmental provisions remain rhetorical and subordinate to economic interests, the laws contain a narrow definition of wetlands and contemplate relatively weak penalty provisions (Kim 2011).

Uganda's regulations require a wetland resource use permit for certain activities in wetlands, such as brickmaking, drainage, aquaculture, and commercial exploitation of wetland resources (Gardner 2003). The regulations exempt other activities such as harvesting papyrus and collecting water for domestic use (Gardner 2003).

Australia's national government has relatively weak authority over purely domestic environmental matters (Gardner 2003). It has been able to assert more authority pursuant to its international obligations, such as the Ramsar Convention. Government approval is required for any action likely to have a significant impact on the ecological character of a Ramsar wetland, and management plans for these wetlands must outline restoration or rehabilitation. These national permit, however, apply to only the limited set of designated Ramsar wetlands. Local regulations fill in some of the gaps from the national level.

Environmental Trading Markets

Many permit-based regulatory systems require the permittee to mitigate wetland impacts resulting from the permitted activities. A pitfall of compensatory mitigation for wetland loss is that it often requires the assumption that the restoration is effective (Gardner 2003). As an alternative, mitigation banking provides front restoration, creation, enhancement, or preservation of wetlands to provide compensatory mitigation in advance of the impacts authorized by a permit (Gardner 2003). An incentives-based market emerges as permittees create their own mitigation banks and entrepreneurial banks, or commercial banks, and sell mitigation credits to permittees seeking to satisfy a mitigation condition (Gardner 2003).

Compensatory mitigation is generally disfavored. The United States and Canada implement a mitigation hierarchy that considers avoidance and minimization before compensatory mitigation. The European Union uses a sequential order where compensatory measures are considered only after defining the specific adverse impact to a Natura 2000 site. A disadvantage to mitigation banking is that promised mitigation projects may fail to replace the functions of the original wetlands (Gardner 2003). Other pitfalls include lack of clear performance standards, lack of monitoring or enforcement, and little long-term maintenance (Gardner 2003). Benefits of mitigation banking include more consistent management of wetland restoration or remediation efforts at designated, pre-approved sites.

Future Challenges

A major challenge for effective permit schemes is overcoming the general failure to avoid wetland impacts despite contrary stated policy preferences, which has resulted in an overall decline in the number and quality of natural wetlands (Clare et al. 2011). Successful wetland regulatory permit programs will clearly state the permit scheme's goals and objectives, include an educational and public participation component, and provide for monitoring and enforcement to ensure compliance (Gardner 2003). Creating permit schemes that encompass these goals is a major challenge, even in countries that already implement a wetlands permit program. Studies on the effectiveness of the US permit program indicate that despite the broad goals of the Clean Water Act, the regulatory framework does not adequately recognize wetland values (Adler 2013).

The international agreements described above promote education by informing governments and their citizens about the importance and values of wetlands. Still, more understanding is needed, as evidenced by the continued destruction of wetlands worldwide.

Major challenges for developing effective permit schemes also include limited government resources and authority. For developing countries and countries in economic transition, the Ramsar Convention's "Small Grants Program" provides funds to create financial incentives for wetland restoration (Gardner 2003). The 2014 recipients include the Hawizeh Marsh (part of the Mesopotamian Marshes), Kenya (to adopt a nationwide wetland policy), Darlen Province (Punta Patino), and the Polesle region (Shatsk Lakes, Perebrody Peatlands, Polissia Mires, and Desna River Floodplains). Governments also may lack the necessary authority to implement a permit scheme. Debate continues in the United States as to the scope of federal jurisdiction under the Clean Water Act to require a permit for dredging or filling activity, especially when it concerns private land. Creative solutions are necessary to overcome these obstacles.

Avoid-Mitigate-Compensate Sequence: Wetland Conservation

115

Royal C. Gardner

Contents

Abstract

The avoid-mitigate-compensate sequence is a common approach to wetland conservation. It has been recognized at the international level in various Ramsar Convention documents and in other multilateral fora. The avoid-mitigate-compensate sequence is also a regular feature of many countries' environmental laws and policies, often using interchangeable correlated terms that are essentially consistent. In the wetland context, the avoid-mitigate-compensate sequence can be an important tool for maintaining the ecological character of wetlands. Such an approach may sometimes be related to a "no net loss" objective.

Introduction

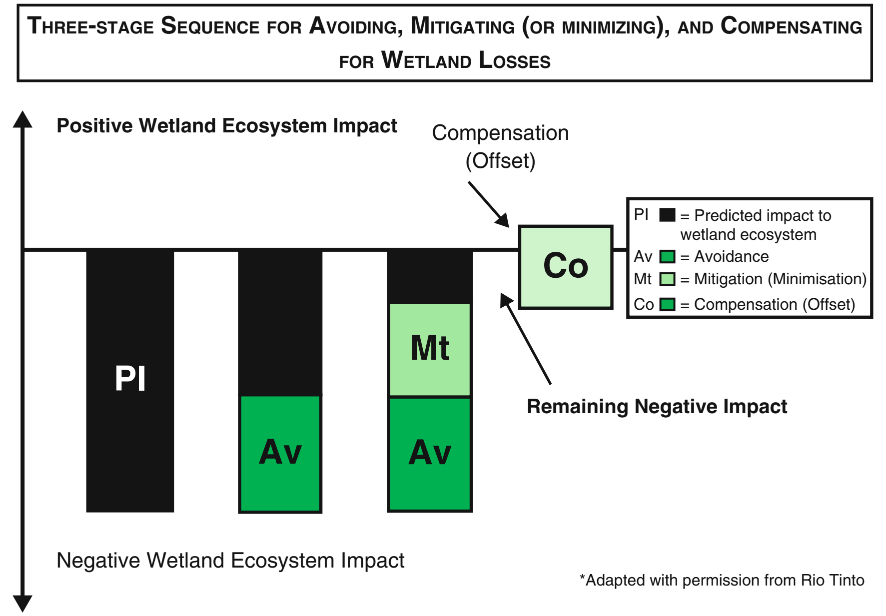
The avoid-mitigate-compensate sequence is a common approach to wetland conservation. It has been recognized at the international level in various Ramsar documents and in other multilateral fora (Ramsar Convention Conference of the Parties 2012; International Finance Corporation 2012). The avoid-mitigate-compensate sequence is also a regular feature of many countries' environmental laws and policies (Gardner et al. 2012). While not all of these countries use the precise avoid-mitigate-compensate formulation, they use interchangeable correlated terms that are consistent in essence. In the wetland context, the avoid-mitigate-compensate sequence can be an important tool for maintaining the ecological character of wetlands. Such an approach may sometimes be related to a "no net loss" objective.

The Avoid-Mitigate-Compensate Sequence

The Ramsar Convention Conference of the Parties (2012) has generally defined the term "avoidance" to mean "*. . .proactive measures to prevent adverse change in a wetland's ecological character through appropriate regulation, planning or activity design decisions. Examples would include choosing a non-damaging location for a development project, or choosing a 'no-project' option when the risks to the maintenance of ecological character are assessed as being too high*."

If impacts cannot be avoided then, under this sequence, mitigation should occur. "Mitigation" as defined by the Ramsar Convention Conference of the Parties (2012) involves "*. . .reactive practical actions that minimize or reduce* in situ *wetland impacts*." Ramsar Convention Resolution X.17 (2008) provides examples such as "*. . .changes to the scale*, *design*, *location*, *siting*, *process*, *sequencing*, *phasing*, *management and/or monitoring of the proposed activity*, *as well as restoration or rehabilitation of sites*." Mitigation actions can take place in situ or ex situ, as long as their effect is realized in the site where change in ecological character is likely. The Ramsar Convention Conference of the Parties (2012) has noted that "*. . .*[*i*]*n many cases it may not be appropriate to regard restoration as mitigation*, *since doing so represents an acknowledgement that impact has already occurred*: *in such cases the term* "*compensation*" *may be a truer reflection of this kind of response*."

If unavoidable impacts cannot be minimized, the next step in the sequence is compensation. The Ramsar Convention Conference of the Parties (2012) views "compensation" as "*. . .actions that are intended to offset the residual impacts on wetland ecological character that resite wetland restoration or creation project*, *provided it adds value beyond what would have happened otherwise* (i.e., *relying on an already-planned benefit would not constitute compensation*)." From a wise use perspective, it is preferable to compensate for wetland loss with wetlands of a similar type and in the same local water catchment (Ramsar Convention ResolutionVII.24, 1999). It is also preferable if the compensation is in place prior to impacts to reduce temporal losses of ecosystem functions and services (Ramsar Convention Conference of the Parties 2012).



Three-stage Mitigation Sequence Chart: Rio Tinto, 2008. Rio Tinto and biodiversity: Achieving results on the ground. Rio Tinto's Biodiversity Strategy. Available at: http://www.riotinto.com/documents/ReportsPublications/ RTBidoversitystrat-egyfinal.pdf.

Fig. 1 Avoid-mitigate-compensate sequence (Adapted from McKenney and Wilkinson 2015; reproduced with permission of The Nature Conservancy)

Thus, as illustrated below in the figure (Fig. 1), reproduced from Gardner et al. (2012), the avoid-mitigate-compensate sequence lays out a stepwise approach. It emphasizes that negative wetland impacts should be avoided if at all possible. If such negative impacts cannot be avoided or prevented, actions should be taken to mitigate (minimize or reduce) this wetland loss or degradation. Finally, if wetland loss or degradation remains after such mitigation, actions should be taken to compensate for (i.e., offset) these residual impacts.

For further information and examples in national laws and policies, refer to Ramsar Scientific and Technical Review Panel Briefing Note Briefing Note 3 (Gardner et al. 2012), from which this entry is adapted.

116 Avoiding Loss of Agricultural Subsidies: Swampbuster

L. Leon Geyer and Dan Lawler

Contents

Abstract

Throughout past centuries, wetland loss has developed into a serious issue that carries profound environmental, economic, and political implications in the United States. The lower 48 states have lost an estimated 53% of their original wetlands over the last 200 years, largely because the United States' agricultural sector has grown and developed, a profound amount of wetlands have been converted into cropland in order to capitalize on their fertile, nutrient-rich soils. This diminishes the capacity of ecosystems to generate a wealth of beneficial services. Historically, economic incentives embodied in agricultural statutes have influenced wetland decline by increasing short-term profitability. To reverse this trend, efforts to protect wetlands were implemented through the Highly Erodible Land Conservation and Wetland Conservation Compliance provisions – widely known as "Swampbuster" – as a part of the 1985 US Food Security Act. Along with key amendments in the Food, Agriculture, Conservation, and Trade Act of 1990, the statute encourages crop producers to conserve wetlands through finan-

Introduction

Throughout past centuries, wetland loss has developed into a serious issue that carries profound environmental, economic, and political implications in the United States. According to the Natural Resources Conservation Service (NRCS), the lower 48 states have lost an estimated 53% of their original wetlands over the last 200 years (NRCS 2013), largely because as the United States' agricultural sector has grown and developed, a profound amount of wetlands have been converted into cropland in order to capitalize on their fertile, nutrient-rich soils. This deprives ecosystems of the "environmental functions of wetlands, such as flood control, sediment control, groundwater recharge, water quality, wildlife habitat, recreation, and esthetics" (NRCS 2013) and occurs because "historically, the economic incentives embodied in agricultural statutes have influenced wetland decline by increasing the profitability while reducing the risks of agriculture" (DOI 2013). In order to reverse this trend, efforts to protect wetlands were implemented through the Highly Erodible Land Conservation and Wetland Conservation Compliance provisions – widely known as "Swampbuster" – as a part of the 1985 Food Security Act. Along with key amendments in the Food, Agriculture, Conservation, and Trade Act of 1990, the statute encourages crop producers to conserve wetlands through financial incentives, substantially changing the working relationship between farmers and their lands. In order to effectively display how the loss of agricultural subsidies relates to wetlands, this article will detail specific Swampbuster provisions, identify their strengths and weaknesses, and discuss future challenges that affect Swampbuster's role in environment, agriculture, and politics.

Swampbuster Provisions

In the United States' agricultural sector, price volatility for commodities presents a significant threat to farmers' profitability, exposing them to a high degree of risk. In order "to make effective risk management decisions, crop producers must integrate farm programs and crop insurance alternatives in a comprehensive risk management decision-making framework" (Lubben et al. 2013), stressing the importance of agricultural subsidies and federal farm benefits in maintaining revenue stability. Swampbuster provides a financial disincentive against the conversion of wetlands to agricultural use by making farmers who do convert wetlands “ineligible for all or a portion of certain USDA program benefits, including loans, subsidies, crop insurance, and price support programs” (USFWS 2003). According to the US Fish and Wildlife Service, conversion of a wetland specifically refers to the “draining, dredging, filling, leveling, removing woody vegetation, or other means for the purpose, or to have the effect of, making possible the production of an agricultural commodity” (USFWS 2003). It is important to note, however, that farmers who converted wetlands prior to December 23, 1985 are exempted from Swampbuster regulations and that farmers can regain eligibility for program benefits if they restore their wetland or effectively mitigate the functions and values of the former wetland (USFWS 2003). Thus, farmers are motivated to conserve wetlands by avoiding the loss of agricultural subsidies.

In order to remedy some of the weaknesses of the original 1985 Swampbuster provisions, the Food, Agriculture, Conservation, and Trade Act (FACTA) was passed in 1990, making some important changes to the statute. According to the DOI, “under FACTA, altering a wetland triggers the Swampbuster sanctions whether or not an agricultural commodity is planted,” increasing the amount of wetlands conserved on agricultural lands (DOI 1994). In addition, FACTA scales penalties according to the severity of the violation, making the statute more accommodating to the high degree of circumstantial variability from case to case (DOI 1994).

Effectiveness

The NRCS estimates that about 87% of wetland losses from the mid-1950s to mid-1970s were due to agricultural conversion (NRCS 2013). Swampbuster has been very effective in limiting this trend, as an article published in *Ecological Applications* argues that “declining rates of net loss have been attributed to the introduction of wetland regulation in the mid-1980s” (De Steven and Lowrance 2011). Statistics from the NRCS support this contention, as “the wetland conservation provisions have sharply reduced wetland conversions for agricultural uses, from 235,000 acres per year before 1985 to 27,000 acres per year from 1992 through 1997” (NRCS 2013).

Although Swampbuster has significantly limited wetland-to-cropland conversions, it does have deficiencies that weaken its efficacy. The first, according to the Department of the Interior (DOI), is that the statute provides an exemption for the conversion of artificial wetlands (DOI 2013). This allows crop producers to convert man-made wetlands into cropland without fear of farm program ineligibility, leaving areas like California’s Central Valley vulnerable to environmental degradation due to their high proportion of artificial wetlands (DOI 1994). Another deficiency that weakens the environmental conservation compliance provisions is that “the particular subsidies extended to growers of sugarcane were not among the Act’s sanctions”

(DOI 2013). This allows farmers to convert wetlands into sugarcane fields without losing farm program eligibility, although this exemption has had a limited effect because sugarcane made up only 0.29% of the total area of cropland harvested in the US in 2012 and is only produced in Florida, Hawaii, Louisiana, and Texas (National Agriculture Statistics Service 2013).

Future Challenges

Despite its overall effectiveness in preventing wetland loss, there are some future challenges that could pose problems for Swampbuster. The first concerns the reduction or elimination of direct payments from the federal farm commodity program. According to the USDA's Economic Research Service, if direct payments are eliminated or reduced, "compliance incentives would be reduced on many farms, potentially increasing environmental quality problems" (Claassen 2012). This suggests that less crop producers would conserve their wetlands because the financial reward for doing so would be significantly lowered, although cutting direct payments would likely only happen if Congress attempts to lower the federal deficit or if a government shutdown prevented the passing of a farm bill.

Compensation in Wetlands

117

Royal C. Gardner

Contents

Abstract

Compensation in the wetland context generally refers to actions taken to offset residual impacts of activities that adversely affect wetlands. Compensation will typically occur as the third stage of the avoid-mitigate-compensate sequence; that is, compensation is utilized when a development project cannot avoid wetland impacts, and steps to mitigate or minimize those unavoidable impacts do not reduce the impact level to zero or some minimal threshold. Depending on the jurisdiction, compensation may also be called an offset or compensatory mitigation or similar terms. A compensation requirement can be part of a policy that seeks to achieve an overall "no net loss" of wetland area and/or function. For example, regulations promulgated by the US Environmental Protection Agency and US Army Corps of Engineers (2008), the wetland regulatory agencies under the US Clean Water Act offer working definitions.

Introduction

Compensation in the wetland context generally refers to actions taken to offset residual impacts of activities that adversely affect wetlands. Compensation will typically occur as the third stage of the avoid-mitigate-compensate sequence; that is, compensation is utilized when a development project cannot avoid wetland impacts and steps to mitigate or minimize those unavoidable impacts do not reduce the impact level to zero or some minimal threshold. Depending on the jurisdiction, compensation may also be called an offset or compensatory mitigation or similar terms (Gardner et al. 2012).

A compensation requirement can be part of a policy that seeks to achieve an overall "no net loss" of wetland area and/or function. For example, regulations promulgated by the US Environmental Protection Agency and US Army Corps of Engineers (2008), the wetland regulatory agencies under the US Clean Water Act offer this definition:

> "Compensatory mitigation means the restoration (re-establishment or rehabilitation), establishment (creation), enhancement, and/or in certain circumstances preservation of aquatic resources for the purposes of offsetting unavoidable adverse impacts which remain after all appropriate and practicable avoidance and minimization has been achieved."

The Figure below (US National Research Council 2001) illustrates the placement and relationship of compensation in the avoid-mitigate-compensate sequence required by the US Clean Water Act (Fig. 1).

Fig. 1 Avoid-Mitigate (Minimize)-Compensate sequence required by US Clean Water Act (Image credit: M Everard © copyright remains with the author)

The Ramsar Convention Conference of the Parties (2012) has adopted a similar definition of compensation:

> "*Compensating for wetland impacts refers to actions that are intended to offset the residual impacts on wetland ecological character that remain after any mitigation has been achieved. An example of compensation would be an on-site or off-site wetland restoration or creation project, provided it adds value beyond what would have happened otherwise (i.e., relying on an already-planned benefit would not constitute compensation). Contracting Parties have emphasized the fact that it is preferable to compensate for wetland loss with wetlands of a similar type and in the same local water catchment (Resolution VII.24, 1999), and priority should be given to on-site compensation*."

Other entities contemplate that compensation may in some cases result in a net gain of biodiversity. The Business and Biodiversity Offsets Program (BBOP), which has applicability beyond wetlands, is a diverse collaborative effort that consists of more than 75 companies, financial institutions, governments, civil society organizations, and individuals. BBOP (2012) defines offsets as:

> "*...measures taken to compensate for any residual significant, adverse impacts that cannot be avoided, minimised and / or rehabilitated or restored, in order to achieve no net loss or a net gain of biodiversity. Offsets can take the form of positive management interventions such as restoration of degraded habitat, arrested degradation or averted risk, protecting areas where there is imminent or projected loss of biodiversity.*"

Compensation Methods

To strive for equivalency between residual impacts and compensation, it is necessary to use the same assessment method for both impact and compensation sites. If a policy objective is functional replacement, then in-kind compensation or offsets should be preferred. Thus, if a development project causes unavoidable impacts to ephemeral wetlands, the compensation (whether it be restoration, enhancement, creation, or preservation) should involve ephemeral wetlands.

Compensation ratios or other credit assessment methods can affect the amount of compensation that must be provided. Such approaches "*...may be used to adjust for the relative quality of impact sites and [compensation] projects; to account for temporal losses; the distance between the [compensation] and the impact sites; and/or to factor in the uncertainty associated with a [compensation] site*" (Gardner et al. in press).

A compensation project can be delivered through a variety of mechanisms. The developer may undertake the compensation project itself or hire an environmental consultant to do so. In some jurisdictions (such as the USA), this is considered "permittee-responsible" compensation because the developer (permittee) remains legally responsible for the compensation project's outcomes.

Another compensation mechanism is wetland banking, which is also called wetland mitigation banking. As Ramsar Resolution XI.9 explains, it is:

> "*...a tool for providing wetland compensation to offset unavoidable impacts that remain after mitigation measures. It is most well developed in the USA, where it is viewed as an incentive-based approach to wetland protection. In its simplest form, a site owner generates compensation credits through the restoration, enhancement, creation, and/or preservation of wetlands. The amount of credits generated is based on the ecological improvements at the site. Credits are then sold to developers to offset adverse wetland impacts to the same type of habitat elsewhere*."

A significant feature of a wetland banking scheme is that the legal responsibility for the compensation shifts from the developer to the mitigation bank operator (Gardner 2011).

A third compensation mechanism, known as in-lieu fees or fee mitigation, also involves a shifting of legal responsibility. (The fees are paid in lieu of the developer providing compensation itself, hence the name.) In such a scenario, an in-lieu-fee administrator would collect and pool monies from developers to conduct compensation projects, generally after development impacts. The timing of the compensation is a significant factor distinguishing wetland banks and in-lieu fees. Wetland bank credits are released only after certain performance standards are met and the on-the-ground ecological replacements are usually provided closer in time to the impacts. With permittee-responsible compensation and in-lieu-fee arrangements, the lag time between impacts and offsets is typically greater (Gardner 2011).

All types of compensation raise concerns, such as those related to long-term stewardship of compensation sites. Although a number of countries have adopted "no net loss" policies that include compensation requirements, there have been a few studies assessing the effectiveness of these approaches (Ramsar 2012). Indeed, assessments in the USA have found that the goal of no net loss of wetlands is not being achieved, especially with respect to wetland functions, due in part to failure of permittee-responsible compensation projects. For example, the US National Research Council (2001) reported that "*...the goal of no net loss of wetlands is not being met for wetland functions by the compensation program, despite progress in the last 20 years*".

While a later US study reported a net gain in national wetland area from 1998 to 2004, it emphasized that this did not translate to a net gain in wetland function (Dahl 2006). Data did not exist to support such a conclusion. Moreover, Stedman and Dahl (2008) subsequently noted that during this timeframe certain regions (such as the southeastern US) and certain types of wetlands (such as forested wetlands) had lost area. These findings led the Ramsar Convention Conference of the Parties and others to reemphasize the importance of avoiding wetland impacts in the first instance (Ramsar 2012).

Note that compensation in this context does not refer to compensation or money to be paid to property owners (called in the US "just compensation" for example) when environmental laws or regulations are deemed to unduly infringe upon private property rights.

Mitigation Banking for Wetlands

118

Mark Everard

Contents

Abstract

The concept of mitigation banking relates to the "banking" of habitat preserved, enhanced, restored, or created, which may then be used to offset harm to other nearby habitats from development activities, particularly to a wetland, stream, or habitat conservation area. The intended outcome is to replace like-for-like the functions and values provided by wetland habitats that may be converted or otherwise adversely affected by proposed development activities. Under mitigation banking, "banked" wetland enhancement or creation schemes can be sold to development proponents as habitat compensation required by enforcement agencies. The USA has been a leading nation in implementing mitigation banking.

Introduction

The concept of mitigation banking relates to the “banking” of habitat preserved, enhanced, restored, or created, which may then be used to offset harm to other nearby habitats from development activities, particularly to a wetland, stream, or habitat conservation area (US EPA n.d.-b). The intended outcome is to replace like-for-like the functions and values provided by wetland habitats that may be converted or otherwise adversely affected by proposed development activities. Under mitigation banking, “banked” wetland enhancement or creation schemes can be sold to development proponents as habitat compensation required by enforcement agencies. The USA has been a leading nation in implementing mitigation banking.

Mitigation Banking in the USA

In the United States, federal agencies as well as many state and local governments are obligated under section 404 of the Clean Water Act (US EPA n.d.-a) to require mitigation for the disturbance or destruction of wetland, stream, or endangered species habitat. Once approved by regulatory agencies, a mitigation bank may sell credits to developers whose projects will impact these various ecosystems.

Credits are units of exchange defined as the ecological value associated with converting to other economic uses a naturally occurring wetland or other specific habitat type. Mitigation credits to compensate for riparian impacts may be assigned in relation to the linear distance of a stream functioning at the highest possible capacity within the watershed of the bank.

What Is a Mitigation Bank?

In the USA, a mitigation bank is a wetland, stream, or other aquatic resource area that has been restored, established, enhanced, or (in certain circumstances) preserved for the purpose of providing compensation for unavoidable impacts to aquatic resources permitted under Section 404 of the Clean Water Act or a similar state or local wetland regulation (US EPA n.d.-a). A mitigation bank may be created when a government agency, corporation, nonprofit organization, or other entity undertakes these activities under a formal agreement with a regulatory agency. Mitigation banks have four distinct components:

- The bank site: the physical acreage restored, established, enhanced, or preserved
- The bank instrument: the formal agreement between the bank owners and regulators establishing liability, performance standards, management and monitoring requirements, and the terms of bank credit approval
- The Interagency Review Team (IRT): the interagency team that provides regulatory review, approval, and oversight of the bank

- The service area: the geographic area in which permitted impacts can be compensated for at a given bank

Details of how this process operates can be found in the US EPA (n.d.-c) *Compensatory mitigation resources* guidance, which specifies that "For unavoidable impacts, compensatory mitigation is required to replace the loss of wetland and aquatic resource functions in the watershed. Compensatory mitigation refers to the restoration, establishment, enhancement, or in certain circumstances preservation of wetlands, streams or other aquatic resources for the purpose of offsetting unavoidable adverse impacts." This is effected as the third phase of a "mitigation sequence."

The Mitigation Sequence

Compensatory mitigation is actually the third step in a sequence of actions that must be followed to offset impacts to aquatic resources. A 1990 Memorandum of Agreement (MOA) between the Environmental Protection Agency (EPA) and the Department of Army establishes a three-part process, known as the mitigation sequence. The purpose of this mitigation sequence is to help guide mitigation decisions and determine the type and level of mitigation required under Clean Water Act Section 404 regulations:

- Step 1. Avoid: Adverse impacts to aquatic resources are to be avoided and no discharge shall be permitted if there is a practicable alternative with less adverse impact.
- Step 2. Minimize: If impacts cannot be avoided, appropriate and practicable steps to minimize adverse impacts must be taken.
- Step 3. Compensate: Appropriate and practicable compensatory mitigation is required for unavoidable adverse impacts which remain. The amount and quality of compensatory mitigation may not substitute for avoiding and minimizing impacts.

The "avoid-mitigate-compensate" sequence is addressed in more detail elsewhere in the Wetland Book.

Compensatory Mitigation Measures

After addressing firstly the steps of avoiding or minimizing impacts, projects that proceed and will cause adverse impacts to wetlands, streams, and other aquatic resources typically require some type of compensatory mitigation. The Army Corps of Engineers (or approved state authority) is responsible for determining the appropriate form and amount of compensatory mitigation required. Methods of compensatory mitigation include restoration, establishment, enhancement, and preservation:

- Restoration comprises the reestablishment or rehabilitation of a wetland or other aquatic resource with the goal of returning natural or historic functions and characteristics to a former or degraded wetland. Restoration may result in a gain in wetland function or wetland acres, or both.
- Establishment (creation) entails development of a wetland or other aquatic resource where a wetland did not previously exist through manipulation of the physical, chemical, and/or biological characteristics of the site. Successful establishment results in a net gain in wetland acres and function.
- Enhancement covers activities conducted within existing wetlands that heighten, intensify, or improve one or more wetland functions. Enhancement is often undertaken for a specific purpose such as to improve water quality, flood water retention, or wildlife habitat. Enhancement results in a gain in wetland function, but does not result in a net gain in wetland acres.
- Preservation occurs when permanent protection of ecologically important wetlands or other aquatic resources is enacted through the implementation of appropriate legal and physical mechanisms (i.e., conservation easements, title transfers). Preservation may include protection of upland areas adjacent to wetlands as necessary to ensure protection or enhancement of the aquatic ecosystem. Preservation does not result in a net gain of wetland acres and may only be used in certain circumstances, including when the resources to be preserved contribute significantly to the ecological sustainability of the watershed.

Mechanisms for Compensatory Mitigation

Compensatory mitigation for unavoidable wetland impacts may be accomplished through three distinct mechanisms:

- Permittee-responsible mitigation, in which the permittee undertakes restoration, establishment, enhancement, or preservation of wetlands to compensate for wetland impacts resulting from a specific project. The permittee performs the mitigation after the permit is issued and is ultimately responsible for implementation and success of the mitigation. Permittee-responsible mitigation may occur at the site of the permitted impacts or at an off-site location within the same watershed.
- Mitigation Banking: A wetlands mitigation bank is a wetland area that has been restored, established, enhanced, or preserved, which is then set aside to compensate for future conversions of wetlands for development activities. Permittees, upon approval of regulatory agencies, can purchase credits from a mitigation bank to meet their requirements for compensatory mitigation. The value of these "credits" is determined by quantifying the wetland functions or acres restored or created. The bank sponsor is ultimately responsible for the success of the project.

Mitigation banking is performed "off-site," meaning it is at a location not on or immediately adjacent to the site of impacts, but within the same watershed. Federal regulations establish a flexible preference for using credits from a mitigation bank over the other compensation mechanisms.

- In-Lieu Fee Mitigation: Mitigation that occurs when a permittee provides funds to an in-lieu-fee sponsor (a public agency or nonprofit organization). Usually, the sponsor collects funds from multiple permittees in order to pool the financial resources necessary to build and maintain the mitigation site. The in-lieu fee sponsor is responsible for the success of the mitigation. Like banking, in-lieu fee mitigation is also "off-site" but, unlike mitigation banking, it typically occurs after the permitted impacts.

Enforcement: Wetlands

119

Meredith Weinberg

Contents

Abstract

Enforcement of laws and regulations protecting wetlands is an important piece of the proverbial wetlands management puzzle. Enforcement usually works in concert with other actions like identification of wetlands, education on the importance of wetlands conservation, and restoration of wetlands that have been damaged or destroyed. Tools for wetlands enforcement vary greatly, and three examples of such tools are as follows: (1) criminal and civil enforcement of law protecting wetlands; (2) administrative actions ranging from notification to violators of wetlands protections to voluntary agreements requiring restoration and future compliance with wetlands protections; and (3) use of diplomatic relationships to enforce wetland protection measures.

Introduction

Enforcement of laws and regulations protecting wetlands is an important piece of the proverbial wetlands management puzzle. Enforcement usually works in concert with other actions like identification of wetlands, education on the importance of wetlands conservation, and restoration of wetlands that have been damaged or destroyed. Tools for wetlands enforcement vary greatly, and three examples of such tools are as follows: (1) criminal and civil enforcement of law protecting wetlands; (2) administrative actions ranging from notification to violators of wetlands protections to voluntary agreements requiring restoration and future compliance with wetlands protections; and (3) use of diplomatic relationships to enforce wetland protection measures.

Wetlands Enforcement Tools

Criminal and Civil Enforcement of Law Protecting Wetlands

An example of the use of criminal and civil actions to enforce laws protecting wetlands exists in the United States under the federal Clean Water Act. The law was passed in 1972 with the objective "to restore and maintain the chemical, physical, and biological integrity of the Nation's waters" (33 U.S.C. § 1251(a)). Accordingly, the Clean Water Act (along with its regulations, which have the force of law) prohibits "discharging" without a permit any dredged or fill material into wetlands that come under the jurisdiction of the federal government (33 U.S.C. § 1344). Determining whether certain wetlands come within federal jurisdiction (and are thus covered by these prohibitions) can be controversial, based in part on a US Supreme Court decision in 2006. (*See Rapanos v. United States*, 547 U.S. 715 (2006)). In any event, the Clean Water Act provides tools for enforcing its prohibitions on alteration of federal wetlands.

Specifically, the Clean Water Act gives the US Environmental Protection Agency (US EPA) primary authority to enforce the Clean Water Act's prohibition on discharging into federal wetlands without a permit. EPA can enforce wetlands cases by bringing judicial actions in federal courts (through the US Department of Justice). In a civil judicial action, a federal court may order a violator to cease its discharge and to remove fill from a wetland, restore damaged wetlands, or conduct additional remedies and may also assess penalties of up to $51,570 per day, per wetlands violation (33 U.S.C. § 1319(b)). In a criminal judicial action, a federal court may order the same remedies but also may assess fines or sentence a violator to imprisonment if the violation of Clean Water Act wetlands protection was criminally negligent or done with knowing disregard of those protections (33 U.S.C. § 1319(c)).

Like the federal government, many states have laws protecting wetlands which they can enforce through civil and criminal actions. (See, for example, Florida Statute Annotated § 373.430(1)(b) (prohibiting discharge into state wetlands without a permit and providing authority for Florida Department of Environmental

Protection to bring civil or criminal suits against violators of statute)). Although neither US EPA nor the states have the resources to bring a criminal or civil action against every violator of Clean Water Act (or state law) wetland protection measures, both have achieved wetlands restoration in cases in which they have pursued civil or criminal actions. In one example from 2007, the US EPA brought a civil suit against two brothers who discharged into wetlands on their property in Kentucky without a permit. (*See United States v. Cundiff*, 480 F. Supp.2d 940 (W.D. Ky. 2007), *aff'd*, 555 F.3d 200 (11th Cir. 2009)). The court permanently enjoined the defendants from further discharges into the wetlands, assessed a $225,000 penalty, and ordered that the defendants conduct restoration of the wetlands they had damaged. In another example from 2005, the US EPA obtained a guilty verdict in the criminal prosecution of several wetlands violators who filled approximately 260 acres of wetlands and other federal waters without a permit. (*See United States v. Lucas*, Case No. 1:04-CR-00060 (S.D. Miss.), *aff'd*, 516 F.3d 316 (5th Cir. 2008)). The federal court sentenced the violators to prison terms, assessed fines, and ordered them to pay restitution of almost $1.4 million.

Wetlands Enforcement Through Administrative Action

Administrative action is more frequently used in the United States to enforce wetlands protections at both the federal as well as at the state and local level (See for example New York State DEE-6 and DEE-7: Freshwater and Tidal Wetlands Enforcement Policies (stating that "the primary goal of [New York state's wetlands] enforcement policy. . .is to enhance the preservation and protection of. . .wetlands by seeking restoration of wetland benefits and functions lost as the result of illegal activity," and describing the administrative actions that can be taken by the state Department of Environmental Conservation when a person violates state wetlands protections)). Examples of federal or state administrative action range from warning a person that he is violating wetlands laws, issuing a "notice of violation" with or without the threat of penalties, or promulgating administrative compliance orders that require restorative action and assess penalties (Environmental Law Institute 2008). In contrast to many civil or criminal judicial actions, administrative actions tend to have the advantage of quick resolution without the delay of litigation (See *Sackett v. Environmental Protection Agency*, 132 S. Ct. 1367, 1374 (2012), which holds that the US EPA's administrative compliance orders are immediately challengeable in federal court, but noting that administrative orders generally provide a way to notify persons of potential wetlands violations and quickly resolve those violations through voluntary compliance).

In one example of an administrative action used to enforce wetlands protections, in 2006, the US EPA and a wetlands violator voluntarily entered into an administrative compliance order on consent (See In the Matter of Robert E. Cross and Wolf Creek Assocs., Administrative Compliance Order on Consent, EPA Docket No. CWA-08-2007-0006). The order details a history of the violator's discharges into wetlands in Colorado, but the point of the order was "remedial, not punitive," and thus required restoration, enhancement, and preservation of wetlands going forward. The US EPA took the position that these activities were “achievable as a practicable matter through commonly used construction, digging, filling, revegetation, and best management practices.” By voluntarily entering the Administrative Compliance Order (ACO), the violator did not admit liability but agreed to abide by the terms of the order. In essence, by issuing the ACO instead of instituting a civil or criminal action against the violator in federal court, the US EPA was able to achieve wetlands restoration without further delay.

Wetlands Enforcement Through Diplomacy

International treaties are the best example of the use of diplomatic relationships for enforcing wetlands protections. A number of treaties seek to protect wetlands: the Convention on Wetlands of International Importance (“Ramsar Convention” adopted in 1971 and signed in Ramsar, Iran) is probably the best known. However, the Convention on Biological Diversity and the Convention on Conservation of Migratory Species of Wild Animals (both relating to global protection of species and their wetlands habitats) are also influential, as are a number of regional conventions protecting marine environments. Most of these treaties have only one avenue for enforcement: the expectation under international law that signatories will respect their treaty obligations and will suffer diplomatic and political pressure if they do not (Griffin 2012).

With 168 signatories to date, the Ramsar Convention’s mission is “. . .the conservation and wise use of all wetlands through local and national actions and international cooperation, as a contribution towards achieving sustainable development throughout the world” (Ramsar Commision, undated). The Ramsar Convention does not include enforcement of wetlands protection as one of its purposes. Instead, it focuses on designating important wetlands on what is known as the “Ramsar List,” advising on best wetlands management practices, and brokering international cooperation concerning transboundary wetlands and the development projects that may affect such wetlands.

The Ramsar Convention contains no codified enforcement provisions, such as sanctions for destruction or delisting of wetlands. Indeed, the convention allows for delisting of protected wetlands inside a country’s borders where there is an undefined “urgent national interest” (see Convention on Wetlands of International Importance especially as Waterfowl Habitat, Ramsar (Iran), 2 February 1971, Article 2(5)). Ultimately, any enforcement of the convention’s principles relating to wetlands protection and preservation has to rely solely on political influence or diplomatic pressure from the international community, with the exception being possible referral to international courts with the acquiescence of two parties in a dispute (Kunich 2003, p. 68).

Future Challenges

The management of wetlands in the future likely will require a combination of enforcement of existing wetland protection measures in addition to careful thought both about what protections are needed as well as how such protections should be enforced. Close examination of the enforcement tools available today, including both successes and failures, can be a helpful way to start that conversation.

Conservation Reserve Program (CRP): Example of Land Retirement

120

Mark Everard

Contents

Abstract

The US Conservation Reserve Program (CRP) is a nationwide land retirement program operating across the United States. Under the CRP, the US government offers incentives to landholders in areas of agricultural production, buffer areas, and wetlands across the United States, inducing them to enter into contracts to change land use on highly erodible and environmentally sensitive cropland and pasture. The CRP was instituted initially as a means to avert soil erosion in cropland, which was a significant problem in the USA in the 1970s when annual cropland soil erosion losses were estimated at 2–6.8 billion tons. Blowing soil also reduced visibility and air quality, most notably in Gaines County, Texas, as well as making land susceptible to wind erosion and reducing agricultural productivity. In a bid to resolve this problem, the US government formally established the CRP in 1985 following initial trials.

Introduction

The US Conservation Reserve Program (CRP) is a nationwide land retirement program operating across the United States. Under the CRP, the US government offers incentives to landholders in areas of agricultural production, buffer areas, and wetlands across the United States, inducing them to enter into contracts to change land use on highly erodible and environmentally sensitive cropland and pasture. The CRP was instituted initially as a means to avert soil erosion in cropland, which was a significant problem in the USA in the 1970s when annual cropland soil erosion losses were estimated at 2–6.8 billion tons. Blowing soil also reduced visibility and air quality, most notably in Gaines County, Texas, as well as making land susceptible to wind erosion and reducing agricultural productivity. In a bid to resolve this problem, the US government formally established the CRP in 1985 following initial trials.

The CRP has since evolved to address a "bundle" of connected ecosystem services including water management and water quality, biodiversity, and air quality protection. CRP payments support conversion of farmed land to grass, trees, wildlife cover, or other uses providing ecosystem services including surface water quality improvement, wildlife habitat creation, carbon storage, preservation of soil productivity, protection of groundwater quality, and reduction of offsite wind erosion damages.

How CRP works

The CRP (CRP website) operates as a land set-aside/retirement program under which the government, via the US Department of Agriculture (USDA), pays landowners incentives through 10- to 15-year contracts to change the use of specific lots of land for ecosystem service benefits (OECD 2010).

The CRP is now a major payment for ecosystem services (▶ Chap. 131, "Payments for Ecosystem Services") scheme, taking the form of a nationwide land retirement program that represents win-win outcomes for landowners and the American public. Under this program, the US government offers landholders incentives to change land use on highly erodible and environmentally sensitive cropland and pasture in order to secure a targeted range of desirable ecosystem services, effectively acting as a "broker" between landowners and the tax-paying public who will benefit from a range of ecosystem service enhancements.

The "sellers" in this PES market are land-owning farmers who, to be eligible for CRP enrolment, must hold cropland suitable for planting or else marginal pastureland suitable for use as a riparian buffer or similar water quality enhancement purpose. Furthermore, this potential "service provider" must have owned or operated the land for at least 12 months (with some allowance for extenuating circumstances). The "buyer" in this PES market is the US government, comprising four main agencies led by the United States Department of Agriculture (USDA), purchasing environmental services on behalf of the American tax-paying public who comprise the ultimate beneficiaries. The PES market and payment mechanism operates through the Commodity Credit Corporation (CCC), an intermediary corporation controlled by the USDA with whom landowners enter into contracts when enrolling in the program. The other federal players include the Farm Service Agency (FSA: the administrative body that runs the program for the USDA) and the Natural Resources Conservation Service (NRCS) which serves as the technical agency supporting CRP through to implementation on private lands.

General sign-ups to the CRP occur during specified enrolment periods, in which landowners compete nationally to enroll their land by submitting a bid for ecosystem services provided and the costs of management activities securing their provision. These competitive bids are then ranked according to an Environmental Benefits Index (EBI). The EBI quantifies overall benefits, integrating multiple services covering: wildlife habitat, water quality, on-farm production, long-term outcomes beyond the contract period, air quality, and scheme cost. The balance of benefits to costs forms the basis of prioritization, ranking all bids in comparison to each other in any one enrolment period. The FSA selects successful bidders from that ranking, and successful landowners are offered contracts lasting for 10–15 years, providing annual payments based on the agriculture rental value of the land.

This competitive bidding process, in which the landowner bids to maximize public benefit at the lowest cost, makes the CRP the largest and longest-running PES program utilizing inverse auctions in the world. This “reverse auction” process, in which farmers state the value they are prepared to accept for undertaking measures to safeguard or enhance ecosystem services, also minimizes transaction costs. It also focuses on measures and locations in which the greatest gains can be achieved, offering greater efficiency than simpler area-based payments. The repeated offerings mean that the scheme can be adapted to changing knowledge and needs, for example, enabling the targeting of additional ecosystem services each round or adaptively improving procedures to improve outcomes. Also, sellers have the option of whether or not to renew their contracts or to negotiate payments for different land parcels, providing them with flexibility. Contracts of 10–15 years also allow farmers to plan for the long term, assured of an income over the contracted period. Furthermore, target regions for CRP sign-up can be adjusted adaptively by Government to optimize delivery of desirable ecosystem services. The benefits produced by the CRP are genuinely additional, as estimates suggest that 51% of CRP land would be returned to crop production in the absence of CRP payments with a corresponding decline in expenditure on outdoor recreation of as much as $300 million annually in rural areas (Sullivan et al. 2004).

An additional continuous sign-up pathway allows landowners potentially contributing to an identified range of high-priority conservation practices to enroll at any time without competition. However, over 80% of the CRP land is registered using the competitive bidding process. Reflecting ongoing priorities such as food production and rural employment, CRP enrolment is capped at 25% of cropland within any one county and an overall limit of 36.4 million acres (14.7 million hectares) across the country at any one time.

Once contracts are arranged, land management practices are put in place by the landowner. CRP participants are provided with annual rental payments in return for establishing long-term, resource-conserving measures. Cost-share assistance may be provided to participants who establish approved cover on eligible cropland for up to 50% of participants' costs in establishing approved practices. Additional financial incentives of up to 20% of the annual payment for certain continuous sign-up practices may also be offered. If a landowner wishes to terminate a contract early, they are required to pay a penalty fee of 25% on rental payments paid, plus repayment, with interest, of all the funds already paid.

The farmer benefits directly, not merely through additional secure income sources, but also indirectly via reduced soil erosion and greater productivity due to improved air, water, and soil quality. Improved environmental conditions indirectly benefit people living in the local area and downstream in target catchments. The CRP has been found to achieve improvements in water quality and biodiversity, particularly for birds, through reduced pollution from agricultural runoff and increased/improved habitat. Since 1982, the FSA estimates that the CRP has reduced soil erosion by 454 million tons per year; restored 2 million acres (0.8 million ha) of wetlands; sequestered 48 million tons of carbon per year; established 3.2 million acres (1.3 million ha) of wildlife habitat; improved water quality with annual reductions in sediment (220 million tons = 200 million tons); substantially reduced nitrogen and phosphorus in run-off; increased wildlife populations (including, for example, increasing prairie pothole duck populations by 30%); and reduced flood damage.

The success of the CRP has served as a blueprint for similar projects in many other countries.

Future Challenges

Setting CRP rental rates is made more complex by fluctuating commodity prices, the commodity price spike of 2008 resulting in the value to landowners of production being significantly greater than returns from CRP rental rates. Furthermore, low rental rates may result in a correspondingly low recruitment rate of new CRP entrants as well as renewals of existing CRP contracts.

Although soil erosion is now a less significant problem in the USA than it was in the 1970s, the CRP contributing to a substantial reduction, many US rivers, streams, and wetlands remain critically depleted or polluted and biodiversity loss continues overall, despite some successes. This demands ongoing improvements to the CRP in addition to other wider measures to protect these critical natural resources. It is likely that increasingly complex requirements to address more ecosystem services may increase transaction and monitoring costs. Conversely, advances in modeling and data collection could improve the CRP's cost and environmental effectiveness.

Land retirement under the CRP can also contribute to fewer farming-related jobs, lower agricultural production, and inflated land rental rates. However, employment impacts may be reduced by diversification into opportunities provided by enhanced services, including hunting, fishing, and other recreational industries.

Contribution of Wetlands to the Food-Water-Energy Nexus

121

Mark Everard

Contents

Abstract

Since 2010, there has been increasing international interest and activity around "the nexus." The most common articulation of "the nexus" is recognition of the interlinked issues of water, food and energy (including the challenges of a changing climate). This is often considered in the context of emancipation of the "bottom billion" of the world's population from multiple, interlinked dimensions of poverty, as expressed in the Millennium Development Goals and their successor Sustainable Development Goals, but also in terms of the resilience of the developed world. The nexus approach recognizes the practical impossibility of effective management of each of these inherently interlinked elements in isolation, representing a practical step from a historically, narrow focus into a more systemic basis for management and decision-making.

Introduction

Since 2010, there has been increasing international interest and activity around "the nexus." The most common articulation of "the nexus" is recognition of the interlinked issues of water, food and energy (including the challenges of a changing climate). This is often considered in the context of emancipation of the "bottom billion" of the world's population from multiple, interlinked dimensions of poverty, as expressed in the Millennium Development Goals and their successor Sustainable Development Goals, but also in terms of the resilience of the developed world (Hoff 2011).

Systems and the Nexus

Wetlands are of substantial importance for the supply of a wide diversity of beneficial ecosystem services, of which the principal components of "the nexus" (water, food and energy) are a subset. By focusing more narrowly on this subset of interconnected services, representing immediate challenges facing both the developing world as well as the ongoing sustainability of the industrialised world, the concept of the nexus has gained considerable political as well as business traction at international, regional and national scales.

Politically, the nexus is seen as playing an important role in increasing resource efficiency, reducing trade-offs, building synergies and improving governance across sectors, emphasising the inevitable linkages between these different aspects (Allouche 2014). For example, unless there are significant changes to the ways that humanity produces and consumes, agricultural production will have to increase by about 70% by 2050, and about 50% more primary energy has to be made available by 2035; these increases would have far-reaching implications for water and land resources, with climate change acting as a further aggravating factor (Hoff 2011). These threats apply equally to rural people living most directly resource-dependent lifestyles as to the viability of developed world enterprises, built environments and the ongoing wellbeing of people living within them. The UN in particular is expressing interest in the nexus (for example UN Water 2014).

The nexus concept is also beginning to influence the thinking of some leading industrial sectors, which recognise that water, food and energy are pieces of the same puzzle and that it is therefore not practical to look at them in isolation (World Business Council for Sustainable Development 2009). Water shortages, for example, are recognised as posing both a direct resource threat as well as compromising supplies of food and farmed goods, the viability of water-intensive business activities such as paper pulping, irrigated farming and mining, and affecting power production.

Wetlands and the Nexus

Wetlands play multiple, interrelated roles across the nexus. These include significant roles in producing and regulating aspects of the nexus, as well as mitigation of impacts upon them.

Wetlands and Water

Wetlands play a key role in water capture, storage and purification, supporting a range of livelihoods from subsistence needs to industrial and power production. They also buffer extremes of flow brought about by catchment conversion for food production and other forms of land appropriation for forestry, urban, industrial or infrastructure purposes, as well as hydrological anomalies resulting from extremes of weather driven by climate change. Wetlands also process pollutants introduced into water systems by food production and other human activities.

Wetlands and Food

Wetlands are exploited directly for a range of food from fish to plant, wildfowl and other items. This includes both wild harvesting, for example capture fisheries or foraging, as well as modifications to increase the efficiency of food production, such as flood-retreating agriculture and finger ponds to trap fish. Wetlands are also frequently converted for more intensive food production, which is one of the principal drivers of the global loss and degradation of wetlands and the diversity of interconnected services they provide (including the narrower set addressed by the nexus). Wetlands also serve important roles in regenerating soils and cycling nutrients, supporting the productivity of connected terrestrial and open water habitats. There are clearly multiple conflicts between the conversion of wetlands for the narrow purpose of food production and the wider set of ecosystem services that they potentially provide.

Wetlands and Energy

Wetland products such as timber, peat and reeds may be used for both home- and industrial-scale energy production. At industrial scale, conversion of wetlands for palm oil production to supply biofuel is placing major pressures on tropical peatlands, which are being drained with the oxidation of peat then releasing substantially more sequestered carbon than is achieved in reductions in vehicle emissions. This illustrates the need for systemic thinking and policy-making, if one narrowly framed good intention (a mandatory biologically derived component in vehicle fuels to reduce net emissions of fossil fuel-related greenhouse gases) is not to result in wider unintended negative consequences for related greenhouse gas emissions as well as disruption of natural ecosystems and water cycles, food production and connected livelihoods.

Water flows are increasingly also being captured by dams and other forms of impoundment for multiple purposes including hydropower generation. Today, hydroelectric energy accounts for approximately 18% of the world's electricity supply (World Bank 2014). Brazil produces more than 90% of its electricity from hydropower projects. Whilst hydroelectric power is inherently renewable, plugging into natural fluxes of energy within the water cycle, it is not however automatically sustainable due to a wide diversity of connected environmental and social impacts. Compared to traditional fossil fuel-based generation, hydropower generation has a different profile of contribution to climate change, air pollution, acid rain and ozone depletion. However, the containment of natural flows also automatically constrains flows of the other important things that water carries – nutrients, sediment, organisms and many more attributes besides – that can have adverse implications for the production of food and energy, access to clean water resources and the ecosystems that provide them downstream in catchments and in the wider landscape. In addition, net claimed greenhouse gas savings from hydropower generation are substantially undermined by methane emissions from anaerobic habitats in deep reservoirs. Although formerly largely ignored, these methane emissions may be highly significant; as much as 104 +/- 7.2 Tg (million metric tonnes) of methane are produced each year from the world's large dams based on ICOLD (International Commission on Large Dams) inventories (Lima et al. 2007), contributing as much as 4% of global greenhouse gas emissions (International Rivers 2007). Although the debate surrounding this issue is vociferous, it highlights conflicts between the conversion of catchments and other wetland systems for the narrow purpose of energy generation and the wider set of ecosystem services that they provide.

Wetlands and Climate Change

As the above considerations demonstrate, the roles of different wetlands types in regulating but also mitigating climate change are as diverse as they are potentially substantial. Some forms of wetland, such as peatlands and wet forests, are amongst the most efficient habitats in terms of carbon sequestration, but equally will release substantial amounts of stored climate-active gases if degraded. They also offer additional beneficial services such as the buffering of spate flows resulting from climate change-induced factors.

Wetland systems can also be significant in affecting microclimate, as one facet of how their associated ecosystem services potentially contribute to multiple dimensions of the quality of urban environments.

Challenges

The nexus concept has been useful in introducing systemic thinking into areas of policy and business decision-making. Progressive thinking about these necessarily systemic connections is to be encouraged.

However, one weakness of debates about the food-energy-water nexus is that high-priority issues apparent at global and national scales may not reflect local concerns. As one example, water and energy security allied with boosting food security through irrigation are often central arguments behind the instigation of large dams and inter-basin water transfers, yet these heavy-engineering solutions can undermine the livelihoods and rights of often large numbers of local people (World Commission on Dams 2000). This is due to impacts expressed not merely at sites inundated on dam filling, but at far broader scales as a result of disruption of flows of water, solutes, sediment, nutrients, organisms, energy and habitat-forming processes as a result of the impoundment, as well as obstructions to both aquatic and terrestrial migratory species (Everard 2013). This dichotomy of perspectives at different scales can be compounded by monetisation of benefits, which may not take account of how local people connect with the services provided by wetland, water and other natural resources in their day-to-day lives. So the nexus approach is helpful, but is not a substitute for participatory approaches to the management of wetlands and other natural systems.

Nexus thinking is driving awareness of the interconnectedness of different facets of human activities, resource dependencies and vulnerabilities. The key challenge is to continue to accelerate the uptake of increasingly systemic thinking across all policy areas, business decision-making and levels of governance.

Economic Incentives for the Nonregulatory Conservation and Management of Wetlands

122

Bill Watts and Mark Everard

Contents

Abstract

The Ramsar Convention defines wetlands as: "areas of marsh, fen, peatland or water, whether natural or artificial, permanent or temporary, with water that is static or flowing, fresh, brackish or salt, including areas of marine water the depth of which at low tide does not exceed six metres" (article 1.1). Many of the ecosystem services provided by these diverse wetlands are public goods. This means that the goods are not saleable in normal markets constituting willing buyers and sellers. Furthermore, since beneficiaries cannot be excluded from deriving benefits from wetland ecosystem services, they have no incentive to pay. Equally, if the resource owner ("seller") cannot sell the service, they also lack an incentive to maintain a supply of publicly beneficial services. Thus, since many wetlands are private as distinct from public property, there is no compelling

Introduction

The Ramsar Convention defines wetlands as: "areas of marsh, fen, peatland or water, whether natural or artificial, permanent or temporary, with water that is static or flowing, fresh, brackish or salt, including areas of marine water the depth of which at low tide does not exceed six metres" (article 1.1). Many of the ecosystem services provided by these diverse wetlands are public goods. This means that the goods are not saleable in normal markets constituting willing buyers and sellers. Furthermore, since beneficiaries cannot be excluded from deriving benefits from wetland ecosystem services, they have no incentive to pay. Equally, if the resource owner ("seller") cannot sell the service, they also lack an incentive to maintain a supply of publicly beneficial services. Thus, since many wetlands are private as distinct from public property, there is no compelling market incentive to prevent the owner draining or in other senses destructively employing the wetland to maximize private profit.

The Current Status of Market Failure

This externalization of many of the beneficial services that wetlands supply is a market-driven tragedy. This market failure explains why, historically, the world has lost much of its resource of wetlands and other productive habitats. This is augmented by perverse agricultural policies, often driven by a mixture of anachronistic priorities and capture by land-owning interests. For example, "food security" is commonly evoked as a rationale for management of wetlands for narrow self-interest, maximizing food production from ecosystems for which the diversity of other potential services are regarded as valueless because they can't be sold.

The long-term consequence of this is that many wetlands throughout Europe have been destroyed or severely degraded over the last 100 years through such mechanisms as drainage for agriculture and pollution (Jones and Hughes 1993). For coastal wetlands, this is exacerbated by the phenomenon of "coastal squeeze." This is widely witnessed throughout coastal Europe including the East Coast of the United Kingdom where the coastline sinks while sea levels rise, constraining the extent of intertidal wetland margins as they abut hard flood and sea defenses and infrastructure such as port facilities.

Some services are captured by regulatory mechanisms, for example, the EU Habitats Directive, the Wild Birds Directive, and aspects of the Water Framework and Marine Framework Directives. However, implicit in the protection of culturally favored services (particularly habitat for wildlife) is that the value of designated sites is infinite while that in a nondesignated site continues to be unvalued, or at best substantially undervalued. The challenge then is to develop economic incentives for the conservation and management of wetlands, without obstructive regulatory intervention.

The Scale of Current Economic Loss

An indication of at least some of the loss which society has allowed through the destruction of wetlands is provided by TEEB (The Economics of Ecosystems and Biodiversity), which gives minimum and maximum ecosystem values for a number of wetlands types, drawing upon value-transfer based estimates of a "basket" of the services that they provide (TEEB 2013) (TEEB calculations include an estimate of the potentially excludable category of provisioning services – those from which public benefit can be excluded – but for all wetland types this is a small part of the aggregate benefit).

TEEB calculations find a remarkable variation for all habitat types assessed, including: for coral reefs from $US14 to $US1.2 million per ha per year; for coastal systems from €248 to €80k; for mangroves and tidal marshes from $2k to $215; for inland wetlands, including peatlands, from $1k to $45k; and for rivers and lakes from $2k to $13k. (All TEEB figures are expressed in 2007 values.) These large variations in estimates are not surprising due to context dependency. As with housing, wetland location is a highly influential factor. Values deduced for inland and coastal wetlands depend on how many people live close by, the existence of substitute habitats (the more that there are in an area the less valued each is individually), and the income of people living close by. There is also "devil in the detail" with respect to a range of connected issues, such as the exchange rate used in calculations, Purchasing Power Parity (the strength of a particular currency for purchasing equivalent goods), and what is included and excluded from the estimates of service values. However, variance is buffered by the fact that, for most derived values, TEEB reports draw on a significant number of studies. For many wetland types, a median estimate might be a best default estimate of value taking account of a representative 'basket' of services, though care has to be taken in managing the transfer of values due to context dependency; one needs to consider all services in comparable terms.

Some valuation studies of the multiple ecosystem service benefits of coastal wetlands are highlighted in case studies elsewhere in this Wetlands Book, highlighting a number of UK coastal-managed realignment schemes. These include:

The Essex coast, addressed under the EU ComCoast project
Wareham, Dorset
Alkborough Flats, north Lincolnshire
The Steart peninsula, Somerset

Bringing Values into Markets and Decision-Making

A challenge remains to bring these diverse ecosystem service values into markets, or at least to ensure that they influence decision-making. This is important for a number of reasons, including:

- Ethically, exclusion of services from decision-making also excludes beneficiary groups leading to an uneven distribution of beneficiaries and victims of ecosystem management.
- Economically, while narrowly framed management solutions may yield benefits for target services, net impacts on the full spectrum of ecosystem services may have an overall negative benefit-to-cost outcome.
- Ecologically, key ecosystem processes may be lost resulting in ecosystem degradation, including resilience and their capacity to continue to provide important services into the future.

Mechanisms are therefore required progressively to assign values to wetland systems that are not currently regarded as profitable, but which are economic. We have seen early stages of this transition, for example, emerging recognition of the value of wetlands for the "natural" provision of flood risk benefits, as well as sequestering carbon as is beginning to be reflected in emerging carbon markets. Water service provider investment in catchment management to reduce contamination of raw water as a cheaper solution than cleaning up excessive pollution downstream is another example of an emerging market for the water purification services of catchment ecosystems, as exemplified by case studies on New York City's public water supply and the Upstream Thinking program (▶ Chap. 124, "Economics of Wetland Conservation Case Study: Catchment Management for Water Quality") and in the case for managed realignment for flood risk management (▶ Chap. 123, "Economics of Wetland Conservation Case Study: Learning from Managed Realignment").

The managed realignment case studies highlight the extent to which many services remain distant from markets and from decision-making forums. In the case of the Alkborough Flats managed realignment, a wetland system located close to both significant centers of population and historic sources of pollution, overlooked services such as pollution management may be extremely important though evading confident valuation due to a lack of quantification methods. The adjacent Humber estuary receives flows of water and associated pollutants from the heavily industrialized English Midlands, South Yorkshire, and Humberside areas. Nitrate, phosphorus, heavy metals, and micropollutants such as endocrine disruptors and persistent organic pollutants may have significant impacts on aquatic, terrestrial, and human systems including, for example, eutrophication and PBTC (Persistent, Bioaccumulative, Toxic, Carcinogenic as well as mutagenic and reprotoxic effects). Ongoing research led by the UK Water Industry Research group (http://www.ukwir.org.uk/site/web/content/home) demonstrates a high likelihood that many micropollutants will exceed the statutory limits set within the EU Water Framework

Directive (▶ Chap. 71, "European Union Water Framework Directive and Wetlands") throughout much of England and Wales, and it is logical to assume that these problems will also exist elsewhere in Europe and indeed much of the rest of the world with high urban densities. Wetlands may have an important role in addressing this emerging problem, as they can be highly effective in transforming, metabolizing, or sequestering nutrients, metals, and complex pollutants, in addition to providing efficient carbon sequestration processes. There is also potentially a strong economic case for investment in these wetland purification services due not merely to the regulatory status of many of these problematic substances but also the high expense (financially and in carbon and resource terms) and the unpredictability and need for continuous management of traditional end-of-pipe treatment technologies.

Scientific certainty about the efficacy of different wetland types to provide this service is an obstacle for wider uptake, as indeed is entrenched oversight of the unintended negative consequences for nonfocal ecosystem services in traditional, single-concern treatment technologies, but certainly warrants considerable further research. The same principle also applies to many of the services provided by wetlands which are currently not captured by markets or factored centrally into decision-making, including, for example, their roles in soil formation and erosion control, pest management, and landscape aesthetics.

Systemic Recognition of Wetland Ecosystem Services

Another of the current market failures, also reflected in failures of regulation and governance, is that ecosystem services (provided by all habitat types) tend to be regarded and managed in isolation. We have already explored how wetland systems have been degraded due to a narrow focus on food production, but the same principle also applies when they are regarded solely or largely on the basis of other "siloed" services such as their role purely as biodiversity resources, flood risk management assets, or where they are used solely to treat wastewater.

In fact, wetlands can, when managed optimally, provide multiple simultaneous benefits of substantial cumulative value. Everard and McInnes (2013) highlight the role of different wetland types, including, for example, integrated constructed wetlands, urban "green infrastructure," and washlands, as examples of "systemic solutions" (▶ Chap. 179, "Integrated Constructed Wetlands for Water Quality Improvement"). These "systemic solutions" are characterized by low resource inputs, working with ecosystem processes to deliver a portfolio of ecosystem services optimally (rather than maximizing one focal service but overlooking consequences for other services). Wetland management optimized to cover a range of services (amenity, flood risk regulation, habitat for nature, carbon sequestration, microclimate enhancement, green transport routes, noise, and visual buffering, etc.) can be of substantial cumulative benefit, also requiring little management compared to traditional engineered solutions and so representing greater net public benefit.

Of course, legacy regulations, institutional structure, and ring-fenced budgets can frustrate the quest for multibenefit outcomes, focused as they are on narrowly framed outcomes. Nevertheless, real economic gains for society can be achieved when ecosystem services are managed simultaneously, possibly by a consortium of institutions at the system level. This approach may also lead to innovative solutions to intractable, apparently unrelated social problems such as tackling obesity (by providing safe and attractive places near people for exercise) and addressing urban "heat islands," air quality concerns, and local flooding.

Market-Based Instruments

Market-based instruments can act to align stakeholder interests with conservation of wetlands and their multiple services. Use of market-based instruments has attracted a great deal of interest both in the United Kingdom and elsewhere. For example, the UK government explicitly recognizes the potential of market-based instruments to "mainstream" the value of nature into all spheres of societal decision-making (HM Government 2011a).

An early example of the use of market-based instruments was enacted in the United States wherein a developer may apply for a Section 404 permit (to discharge dredged or fill material into the navigable waters at specified disposal sites) issued under the Clean Water Act 1972, which introduces a process of offsetting wetland destructive development through the creation of mitigating essentially restored wetland elsewhere. Similar types of offset processes characterized by the provision of compensation for some form of loss have also been developed in Australia, Costa Rica, and Brazil and are actively being considered elsewhere including exploratory "biodiversity offsetting" schemes in the UK. These offsetting schemes provide payment for the continued maintenance, and potentially the provision of services, from a habitat which remains intact.

"Payments for ecosystem services" (PES) are another form of strongly emerging market-based instrument. PES is founded on the establishment of voluntary markets for ecosystem services, production of which depends upon habitat management that is additional to statutory obligations. The OECD (2010) estimated that there were 300+ PES schemes established globally and that number has escalated substantially since that time. The English government Department for Environment, Food and Rural Affairs (Defra) has an active environmental economics program including promotion of PES, including recent publication of a Payments for Ecosystem Services Best Practice Guide (Smith et al. 2013).

The Defra PES Best Practice Guide notes that:

> "The term PES is used to describe a wide variety of schemes in which the beneficiaries, or users, of ecosystem services provide payment to the stewards, or providers, of ecosystem services. In practice, PES is often used in reference to schemes which involve a continuing series of payments to land or other natural resource managers in return for a guaranteed flow of ecosystem services, or at least management actions likely to enhance their provision..."
>
> "...The basic idea behind PES is that those who provide ecosystem services – like any service – should be compensated for doing so. PES therefore provides a mechanism for

pricing historically undervalued ecosystem services such as water quality regulation and the provision of habitat for wildlife and, in doing so, brings these into the wider economy. The novelty of PES arises from its focus on the 'beneficiary-pays Principle', as opposed to the 'polluter-pays Principle.'"

The scientific knowledge necessary to introduce PES markets from wetland is substantially in place for issues such as carbon sequestration, nutrient cycling, pollution remediation, fisheries, recreation, and floodwater attenuation. Water service provider investment in catchment management to reduce contamination of raw water as a cheaper solution than cleaning up excessive pollution downstream referred to previously (see the case studies on New York City's water supply and the Upstream Thinking program ▶ Chap. 124, "Economics of Wetland Conservation Case Study: Catchment Management for Water Quality") are founded on PES principles, each constituting substantial exemplar programs based on "hard" bottom-line outcomes.

Notwithstanding intense interest in policy, academic, and business circles, Salzman and Ruhl (2002) caution that PES may not always represent an apparent win-win outcome for conservation and development, with significant challenges including ensuring that benefits are genuinely additional and also adequately addressing issues of moral hazard, social justice, and market size and market penetration. PES is no panacea, but it does constitute an additional form of policy instrument. Neither does the emergence of PES as a viable policy instrument abrogate responsibility for regulation. PES design and auditing is critical to avoid unintended negative outcomes for nontarget services and to avoid fraud; a legal process is required to describe the obligations and institutional mechanisms which permit and document transfer of obligations to third parties. Nevertheless, strong case studies around the world (see the water service provider catchment management case studies ▶ Chap. 124, "Economics of Wetland Conservation Case Study: Catchment Management for Water Quality") and progressively evolving "best practice" (such as Smith et al. 2013) are revealing significant benefits that may arise from well-targeted and designed PES markets.

Growing Interest in Internalization of the Value of Wetland Ecosystem Services

There is a global growth in interest in the internalization of the value of ecosystem services into the mainstream of societal decision-making, including those provided by wetlands. For example, the Aichi Targets, adopted by the Convention on Biological Diversity in 2010, contain the target "...by 2020, ecosystems that provide essential services, including services related to water, and [which] contribute to health, livelihoods and well-being, are restored and safeguarded..." (CBD 2013). The EU has adopted the target of halting the loss of biodiversity and the degradation of ecosystem services in the EU by 2020 and restoring them insofar as is feasible. Thus, in 2011, the European Commission adopted a new biodiversity strategy with a commitment to "...promote the development and use of innovative financing mechanisms, including market-based instruments" and states that "Payments for Ecosystem Services schemes should reward public and private goods from agricultural, forest and marine ecosystems" (EU 2011). In England, the Natural Environment White Paper, *The Natural Choice* (HM Government 2011a), emphasizes "...real opportunities for land managers to gain by protecting nature's services, and trading nature's benefits with businesses, civil society and the wider public sector." Further reference to the role of economic instruments to secure water services is contained in the UK Government Water White Paper, *Water for Life* (HM Government 2011b).

This stimulus is also evident among the UK's devolved administrations. A land use strategy for Scotland, *Getting the Best from our Land* (Scottish Government 2011), set out a series of principles for sustainable land use including explicit encouragement of opportunities for land use to deliver multiple benefits. The Welsh Government Green Paper, *Sustaining a Living Wales* (Welsh Government 2012), has a central tenet of moving to an Ecosystem Approach in environmental regulation and management, also highlighting "...genuine opportunities for the market to 'pay for ecosystem health and services'" and cites the example of corporate sponsors investing in woodland creation as a recognized method of sequestering carbon emissions.

Observations in the section above addressing the *Systemic recognition of wetland ecosystem services* are equally valid for PES schemes. Unintended conflicts with nontarget services may occur if there is too narrow a focus on one or a few favored new marketable services and their privileged beneficiaries. Addressing the multiplicity of ecosystem services provided simultaneously by wetlands and other ecosystems, the Defra PES Best Practice Guide (Smith et al. 2013) deals not only with the need to explore the impacts of proposed management on a systemic basis, but also explores opportunities for combining ecosystem services in markets through "bundling" (a single buyer or consortium of buyers pays for a package of ecosystem services), "layering" (multiple buyers pay separately for different ecosystem services), or "piggybacking" (not all ecosystem services are sold but there is a buyer for a single service, or possibly several services, with other services accruing to users free of charge).

Conclusions

Wetlands produce many ecosystem services, a substantial proportion of which are public or "club" goods. These nonmarketed services tend not to be remunerated and thus privately "profitable" when the habitat is owned as private property. Ecosystem services such as flood regulation, carbon sequestration, pollution management, fish nursery functioning, and landscape benefits may tend to be suppressed by private owners in favor of socially and environmentally suboptimal marketed goods and services.

There is a strong political preference for PES-type approaches to ecosystem management as a means to encourage value realization from the ecosystem services provided by wetlands and other habitats, many of which have historically been omitted from both markets and wider societal decision-making. However, an ecosystem service market regime should provide accountability and transparency, be subject to monitoring, be fungible both in the sense of service definition and substitution, and also allow for public participation.

There may be examples where it may be cheaper to acknowledge that, for critical wetland habitats such as intertidal habitats which provide coastal protection among a wide range of other publicly beneficial services, public ownership and collective management may be favorable to private ownership permitting the optimization of multiple, publicly beneficial services rather than maximization of a few privately beneficial goods.

Introduction

The term "coastal squeeze" describes the loss of intertidal wetland habitat, a combined result of a sinking coastline and rising sea levels constraining the extent of intertidal wetland margins as they abut hard flood and sea defenses and infrastructure such as port facilities. This is driving innovation in the management of coastal flooding through such techniques as managed realignment, where land formerly "reclaimed" for agriculture and other uses is allowed to revert to intertidal wetland habitat. As these habitats reform, a range of beneficially and formerly undervalued services such as flood risk regulation, habitat for wildlife including fishery recruitment, nutrient cycling, and characteristic landscapes are restored. This chapter draws lessons about value creation by the recreation of these various ecosystem services drawing upon studies of four managed realignment schemes. Dixon et al. (2007) provides a summary of early experiences with managed realign-
38 ment and the steps needed to optimize habitat creation.

Case Study 1: The ComCoast Project

The EU-funded ComCoast project (ComCoast 2007) investigated the multifunctional ecosystem services provided by intertidal habitats in Northern Europe, exploring more defensible and sustainable approaches to coastal flood defenses including "soft" land management approaches rather than hard engineered barriers. The research analyzed cobenefits for the whole coastal community, in the construction of environmentally and economically sound Flood Risk and Coastal Defence solutions covering a range of ecosystem services, such as fish recruitment, carbon sequestration, water quality, and cultural services.

ComCoast was funded under the EU North Sea Interreg IIIb Programme with key partners in the Netherlands, England and Wales, Germany, Belgium, and Denmark. It included three UK-based PhD studentships examining: (1) fish utilization of managed realignment sites, (2) nutrient capture and carbon sequestration on managed realignment sites, and (3) the economic case for a more integrated approach to estuary management, drawing on the results of the other two science-orientated PhD studies. These PhD studies were based in a number managed realignment sites and mature saltmarshes in the Blackwater and Roach & Crouch estuaries in Essex, in the East of England.

The fisheries research strand of ComCoast (Fonseca 2009) highlighted the links between changes to physical habitat and the resulting societal benefits arising from increased fish stocks relevant to both commercial and recreational fishing. Early work summarized by Colclough et al. (2005) had demonstrated a close association of the early life stages of important commercial species such as sea bass (*Dicentrarchus labrax*) with the existence of high marsh, confirming the provisional findings of French authors (such as Laffaille et al. 2001). These observations are important given the requirements of the EU Water Framework and the Marine Strategy Framework Directives. Fonseca et al. (2011) describe highly dynamic and pronounced seasonal use of the habitats under study, also providing detailed evidence of the early feeding of the bass fry in newly created habitats. An attempt was made during the study period to quantify fish utilization.

The fish survey data fed into an economic analysis, though the weight of this evidence was restricted by the size and amount of time available for fish sampling. This may also help explain the relatively small component the conservative fishery quantification represented in the overall valuation (Luisetti 2009). Clearly, multiyear quantitative data sets would have added more analytical power. Furthermore, commercial (and not recreational) value data were only available for sea bass. Other marine fish species with commercial and/or recreational significance were also observed exploiting experimental saltmarshes, but no valuation data were available for these. (This issue of partial valuation of fish recruitment is covered in detail by Vieira da Silva 2012.) More recent studies of juvenile fish on some of the same Essex sites have also demonstrated high site fidelity over the first summer for young of year sea bass and other species (Green et al. 2012).

Conclusions drawn in the economic study of fish recruitment services were thus low, omitting most species and the higher-value recreational services provided by the affected realignment. If additional benefits arising from fish recruitment on intertidal wetlands can be substantiated scientifically, beyond observation (for example by S. Colclough & W.Watts, pers.obs.), there could well be a case for public funding for the construction or rehabilitation of intertidal habitats through funding mechanisms such as the EU Common Fisheries Policy. Quantification of cobenefits such as coastal flood regulation, amenity, and landscape aesthetics may open up other potential cofunding streams and may justify realignment, even where the potential fishery service is not sufficient, in itself, to make the case.

The nutrient and carbon cycling research strand of ComCoast found that carbon (C) and nitrogen (N) contents in natural intertidal sediments were higher than in managed realignment sediments (Adams 2008). However, mature managed realignment sites possessed C and N burial rates at least as great as natural marshes and, if increased sedimentation in these predominantly low-lying intertidal areas is accounted for, mature managed realignment sites far outstrip natural marsh C burial rates.

Both natural and managed realignment intertidal wetlands were also found to be small sources of the greenhouse gases methane and nitrous oxide (each with a stronger climate-forcing effect than carbon dioxide), offsetting to a limited extent the net climate regulation benefits of carbon sequestration. The observed current carbon sequestration rate at the Blackwater estuary managed realignment sites was ~690 tonnes (metric) of CO_2eq year^{-1} (carbon dioxide equivalents per year).

The economics research within ComCoast highlighted some of values of ecosystem services provided by saltmarshes. It deduced a "willingness to pay" among members of the public polled under the ComCoast program for the creation of new saltmarsh in the Blackwater estuary, accounting for the existence of other saltmarshes in the area and the potential substitution of these alternative saltmarshes by the public in the delivery of wetland services, in their valuation of the worth of a new realignment. Saltmarsh was considered important for amenity and recreation as well as for biodiversity both in terms of access to the site (use value) and improved environmental quality (nonuse value). While there was general public support for saltmarsh recreation, people felt uncomfortable having them too close to their houses. This may be linked to nuisance associated with visitors, though other studies suggest that having water closer to their homes is perceived as a greater risk even though, hydrologically, the risk of flooding in actual fact may be decreased by these now closer but larger floodwater storage areas.

Luisetti (2009) synthesized this "willingness to pay" data with physical science-based fisheries and biochemistry data, producing an overall assessment of the value of various realignment options within the Blackwater estuary. This subsequent study, based on the Composite Environmental Benefit variable which includes both use and nonuse value, found that irrespective of the economic discount rate applied in cost-benefit analysis, a substantial scheme of realignment within the Blackwater was justified.

Potential air quality and water pollution control benefits may also arise from habitat recreated under managed realignment explored in the ComCoast study. However, these purification benefits were not reflected in the benefits elicited, due to scientific uncertainty about the magnitude of these effects. The absence of such data is of course symptomatic of the often low public awareness of far-field environmental effects, even though there may well be substantial potential health benefits to be gained from realignment upwind of urban areas.

The ComCoast project extended knowledge about many of the ecosystem services associated with intertidal habitat recreation through managed realignment, highlighting the need to include all ecosystem services into optimal decision-making about sustainable coastal defense strategies.

Case Study 2: Wareham

The first instance where the ecosystem valuation approach was applied to Flood Risk Management within the UK was at Wareham in 2006 (summarized in Defra 2007). Wareham is located close to two adjacent estuaries of the rivers Frome and Piddle where they enter the western end of Poole Harbour, Dorset, an area of international importance for nature conservation. These estuaries were lined by 50-year-old flood banks, providing some protection against flooding for 42 properties and 400 ha of poor quality grazing marsh.

As the flood defenses were nearing end-of-life, various options were considered for their future management. These included "No Intervention" and "Do Minimum," which would have put people and property at risk as well as adversely affecting existing nature conservation interests, navigation, and rights of way. These issues could have exposed the regulatory authority (the Environment Agency) to litigation. A "Hold the Line" scenario considering rebuilding defenses to maintain the status quo was also found to be economically unsustainable, the expenditure not meeting the Cost Benefit Analysis-based funding criteria of Defra (the relevant UK government department). This left various managed realignment options.

Economic valuation of outcomes for ecosystem services supported the managed realignment approach, setting back smaller-scale flood defenses and allowing the recreation of intertidal habitat. This was supported by local stakeholder dialogue using a simple semiquantitative scoring system to assess the likely magnitude of changes, from significantly positive to significantly negative or unknown, for a range of ecosystem services as a result of these different options. Although the Wareham assessment was equivocal in terms of absolute economic benefits, it indicated a broader balance of costs and benefits associated with a particular managed realignment option and highlighted where further information or research was necessary.

The Wareham study showed that constructive engagement with a wide range of stakeholders is essential to build understanding and support for the results of the process. This was helped considerably by expressing benefits in readily understood ecosystem services terms (amenity areas, protection of farmed land, etc.) evaluated via a simple semiquantitative ecosystem valuation process.

Case Study 3: Alkborough Flats

Everard (2009) led an ex-post ecosystem service analysis of the Alkborough Flats managed realignment on the Humber Estuary. The realignment site includes around 440 hectares of farmed land which was to be periodically inundated on high tides through an engineered breach in the former flood bank. The breach is tightly controlled to protect the adjacent navigation channel that forms an important trading route up the rivers Ouse and Trent. This realignment project was driven by EU Habitats Directive requirements to ensure "no net loss" of habitat, caused both by sea level rise-induced "coastal squeeze" and development elsewhere in the estuary. It is also a flood defense scheme, providing flood storage and thus allowed a delay in the construction of new flood defense structures upstream, yielding a significant benefit through delayed construction costs.

The need to protect the navigation route and create substitute habitat led to suboptimal outcomes from a narrowly flood defense perspective, though the traditional property-saving benefits of the scheme totaled £12.3m over the likely life of the project, which was marginally greater than the aggregate of site acquisition and development costs of £10.2m. Evidently potential flood risk and habitat-related benefits alone would not normally have affected the management of the site by a private owner.

However, the wider lessons from the ecosystem services valuation study reveal a more than doubling of benefit cumulatively from changes in various other ecosystem services, with an approximate aggregate benefit of £23m. This figure excludes some potentially significant values that eluded monetization, including air quality regulation and fish recruitment. These omissions highlight the "missing markets" phenomenon and absent scientific data.

The maximization of marketed outputs prior to realignment to achieve wider public benefits (principally flood risk management and habitat for wildlife) suggests that "provisioning service" values should have fallen after realignment. In fact, Everard (2009) found that the fall in provisioning services related to declining arable production was approximately balanced by gains from rare breed grazing (including sales of meat, wool, breeding stock, and other products). Therefore, it is at least sometimes possible to achieve "win-win" outcomes across ecosystem services when innovative ideas and practices are deployed. This runs contrary to many established assumptions about "win-lose" trade-offs being inevitable when realignment takes place.

Case Study 4: Steart Peninsula

Similar conclusions about positive-sum gains from realignment were drawn in a study of ecosystem service outcomes likely to result from managed realignment of the Steart Peninsular in Somerset, UK (Vieira da Silva 2012; Vieira da Silva et al. 2014). This study demonstrated that "*A conservative, yet considerable, net annual benefit range of £491k to £913k has been deduced*" from combined changes in services.

In agreement with the findings of other ecosystem services case studies, Vieira da Silva (*ibid.*) also notes that many "*. . .research and knowledge gaps exist with respect to several ecosystem services, particularly the supporting services for which market values are clearly elusive. This is of concern as it affects our current ability to quantify and/or value them, and hence to include these important aspects of ecosystem integrity, functioning and resilience into decision-making. . . ...These gaps therefore demonstrate a clear need for further research, both theoretical and through long-term monitoring of these schemes once established.*" Several areas of necessary further research were identified, including the contribution of intertidal habitats to fish recruitment, the net contribution of recruitment to local and national fish stocks, values associated with potential alternative farming systems (shellfish, salicornia, etc.), microclimate effects of coastal wetlands, nutrient burial studies, and the effect of intertidal habitats on micropollutants.

Conclusions

Studies at these four managed realignment sites underline that many of the problems we have with assigning values to wetland systems are not economic, but are a function of absent underlying science as well as societal recognition of these values. Nevertheless, the absence of markets for these often unrecognized services means they are not valued and often, to the extent they are thought about at all, deemed valueless. These four case studies illustrate that these values can be significant and, with the correct policy and/or market instruments, can be exploited for net societal gain.

Economics of Wetland Conservation Case Study: Catchment Management for Water Quality

124

Bill Watts and Mark Everard

Contents

Abstract

Traditional approaches to the abstraction and treatment of water for public supply depend on a range of engineered approaches including dams, interbasin water transfers, and groundwater abstraction, generally with a high reliance on energy- and chemical-intensive treatment processes post abstraction. Substantial energy inputs, associated climate-active gas emissions, chemical inputs and linked supply chain concerns, waste generation including disruptive vehicle movements, and maintenance activities mean that the sustainability of this approach is questionable. These concerns are allied to the risks associated with declining water availability resulting from less predictable weather patterns. Overcoming these problems stemming from a largely reactive and piecemeal approach to water management, a more systematic and ecosystem-based approach is gaining momentum. This takes the form of a catchment-based approach, emphasizing the benefits of controlling contamination of water at source rather than committing greater retrospective investment in more intensive cleanup of water

Introduction

Traditional approaches to the abstraction and treatment of water for public supply depend on a range of engineered approaches including dams, interbasin water transfers, and groundwater abstraction, generally with a high reliance on energy- and chemical-intensive treatment processes post abstraction. Substantial energy inputs, associated climate-active gas emissions, chemical inputs and linked supply chain concerns, waste generation including disruptive vehicle movements, and maintenance activities mean that the sustainability of this approach is questionable. These concerns are allied to the risks associated with declining water availability resulting from less predictable weather patterns.

These problems stemming from a largely reactive and piecemeal approach to water management have led to calls for a more systematic and ecosystem-based approach. This has been translated into a catchment-based approach, emphasizing the virtues of controlling contamination of water at source rather than greater retrospective investment in more intensive cleanup of water abstracted lower in catchments. This transition is driven largely by water quality considerations, though water quantity concerns are increasingly also influencing planning. Although leadership has often been shown by sectors such as NGOs and the water industry, the catchment-based approach is increasingly reflected in government strategies (including, for example, the UK's emerging catchment-based approach: Defra 2013).

Payments for ecosystem services (PES) approaches are emerging rapidly across the world, with markets for water services a common type of novel market. This chapter addresses two case studies – the "Upstream Thinking" program in the south west of England and the New York City water supply – to illustrate how the economics of wetland functioning at landscape scale are being brought into the mainstream of water management activities.

Case Study 1: Upstream Thinking, South West England

Water resource challenges in the south west of England include a shortage of groundwater due to widespread impermeable geology, allied with a substantial rise in population during the summer vacation season when water resources are at their most stressed. This leads to a heavy dependence on abstraction of surface water for public supply, both directly from reservoirs as well as from rivers augmented by releases of stored water. Both sources are vulnerable to contamination from farming activities in this predominantly rural English region.

The "Upstream Thinking" program (http://www.upstreamthinking.org/) is founded on understanding and protecting the functioning of catchment ecosystems as the basis for production of clean water and a range of co-benefits. These have intimate interactions with the practices and economics of working farms which comprise the overwhelming bulk of the catchment area. Upstream Thinking was developed as an innovative, partnership-based program agreed with government under the 2010–2015 UK water industry investment period. It operates by directing a proportion of water service revenues from customer bills as incentives for farm improvements that go beyond statutory requirements, or in other words a classic PES scheme.

The key players in the Upstream Thinking PES market are South West Water (SWW: www.southwestwater.co.uk), the regional water utility, and the Westcountry Rivers Trust (WRT: www.wrt.org.uk). WRT was set up as an environmental charity in 1995 to protect and improve the fresh waters in England's west country. The Trust has, since its inception, developed strong relationships with farm businesses, helping them save money on chemical, water, waste, and habitat management in ways simultaneously advantageous to river health. SWW has long recognized the benefits of working with WRT as a cost-effective means to protect water resources through reducing contamination from farmed land. Under the Upstream Thinking program, WRT serves a key intermediary role between the water company and the numerous farm businesses dispersed throughout key catchments, acting as a "trusted broker" simultaneously addressing practical farming priorities and the vitality of the wider catchment ecosystem. The WRT works with farm businesses to target investment and advice to where it can most efficiently contribute to improvements in catchment (water) quality and quantity. This reduces both the costs and the carbon footprint of water supply. The WRT approach includes the subsidization of a wide range of measures that achieve simultaneous farming and river ecosystem benefits, many of them protecting wetland habitat and associated beneficial functions. Measures include fencing stock away from river banks and wetlands, separating "clean" roof water from "dirty" farmyard water, relocating gates, armoring or bridging stream crossings to avoid silt ingress, and better storage facilities and advice on more economical, targeted application of fertilizers and pesticides.

In calculations audited by Ofwat (the economic regulator of the water and sewerage sectors in England and Wales), Upstream Thinking is expected to deliver a substantial 65:1 benefit-to-cost ratio based on projected improvements to raw water quality and consequent savings on treatment costs alone. This benefits the water industry, including its bill-paying customers. However, multiple additional co-benefits arise through the focus on improved catchment functioning and health. Protection of biodiversity is prominent among these co-benefits, including rare species and salmonid fish stocks which are themselves a valuable resource for angling, as well as enhancement of ecotourism, landscape aesthetics, and the security of the rural economy.

This is "win-win" result, increasing net farming revenue while also saving money for the water utility with savings passed on to customers, achieved in substantial part through targeted protection and restoration of catchment wetland functioning.

Case Study 2: New York City Public Water Supply

A prominent and substantially cost-efficient American example of a PES-based approach to catchment management for water resource protection is seen in the New York City public water supply (see review by Everard 2013). The Department of Environmental Protection of the City of New York delivers over 1.2 billion US gallons (4.5 billion liters) of water daily to 9 million people.

While early residents drew water from local sources, urban growth necessitated accessing remote sources. In 1905, New York City identified the Catskills Mountains as a prime water source, constructing various reservoirs and dams throughout the Catskills through to 1928, also turning in 1927 to additional sources in Delaware County. The Catskills–Delaware system, known as the Cat/Del system, was implemented in stages between 1937 and 1964, today providing New York City with the largest unfiltered surface water supply in the world. However, by the 1980s, industrial-scale agriculture and forestry, tourism, and residential and industrial development posed increased risks to raw water quality, while increasingly stringent public health standards were coming into force. The vast cost of installing expensive filtration plant – $US 4–6 billion (£2.1–3.2 billion at the then-current exchange rates) in capital costs plus annual running costs of more than $US 200 million (£160 million) at 1990 prices – drove city planners to rethink their water supply strategy. Cost-benefit analysis suggested that a comprehensive "watershed protection program" would cost substantially less than filtration.

Putting this into operation would be a tough challenge. Top-down, punitive regulations had generally ended in failure elsewhere. Consequently, city planners opted to explore an urban-rural watershed protection partnership. This offered benefits both to city residents and rural communities in the Catskills and Delaware catchments through improved management of the water-yielding landscape. A process of dialogue, mutual understanding, and consensus-building between farmers and city representatives was consequently instigated. By the end of 1991, an urban-rural watershed protection partnership had been developed including targeted, economically efficient integrated agricultural pollution controls at individual farm business scale backed up by grants, inclusion of forestry interests, land acquisition programs, and ecologically based land management.

By January 1997, the constituent parties formalized a comprehensive Memorandum of Agreement, to which the city committed funds of approximately $US350 million (£190 million) in addition to the costs of various other initiatives in the watershed. The total cost of the watershed protection program was approximately $US1.3 billion (£700 million), a fraction of the capital and operating costs, let alone the wider environmental impacts, of traditional filtration solutions. The partnership approach, linking rural and urban stakeholders into a mutually beneficial arrangement based on the ecosystem services provided by the land, was the key to maintaining the city's pristine water quality as well as the viability of farming for the foreseeable future.

Conclusions

The Upstream Thinking and New York City case studies highlight how investment in protection of important wetland habitats and wider landscape-scale wetland functions can have significant benefits for the economics of public water supply, quantifiable in "hard" financial terms and forming the basis for PES markets. These lessons are augmented by those from the Working for Wetlands (WfW) program in South Africa, where benefits for water availability are linked with biodiversity and also social outcomes that include training and employment for disadvantaged people. In all cases, a wide range of co-benefits arise from better-functioning catchment ecosystems, augmenting both the business and ethical cases for investment in the restoration of catchment wetland functions.

Economics of Wetland Conservation Case Study: "Systemic Solutions" for Integrated Water Management

125

Mark Everard and Robert J. McInnes

Contents

Abstract

Unintended consequences arising from narrow consideration of outputs from water and environmental management technologies are of increasing concern, including, for example, climate-active gases and solid waste generated by increasing intensity of traditional wastewater treatment. Formerly overlooked environmental and financial costs, as well as social concerns along supply chains and local disruption due to vehicle movements, are also giving cause for concern. Broader consideration of inputs and outputs highlights the need for low-input solutions that optimize outcomes across multiple ecosystem services. These "systemic solutions" are defined as "*. . .low-input technologies using natural processes to optimise benefits across the spectrum of ecosystem services and their beneficiaries*."

Introduction

Unintended consequences arising from narrow consideration of outputs from water and environmental management technologies are of increasing concern, including, for example, climate-active gases and solid waste generated by increasing intensity of traditional wastewater treatment. Formerly overlooked environmental and financial costs, as well as social concerns along supply chains and local disruption due to vehicle movements, are also giving cause for concern. Broader consideration of inputs and outputs highlights the need for low-input solutions that optimize outcomes across multiple ecosystem services. Everard and McInnes (2013) explore opportunities for "systemic solutions" are defined as "*. . .low-input technologies using natural processes to optimise benefits across the spectrum of ecosystem services and their beneficiaries*."

Examples of 'Systemic Solutions'

Everard and McInnes (2013) explore progress and further opportunities to build the value of wetland ecosystem functions into water and environmental management systems by examining inputs and outputs associated with a range of ostensibly ecosystem-based techniques:

- Constructed wetlands applied as tertiary "polishing systems"
- A range of urban ecosystem-based technologies (including, for example, SuDS, green infrastructure, water-sensitive urban design, and multifunctional urban river restoration) as reviewed by Everard and Moggridge (2012)
- Washlands
- Integrated constructed wetlands (ICWs)

This analysis revealed a spectrum of "footprints," from those that differ little from conventional electromechanical engineering techniques through to techniques addressing many of the attributes of a "systemic solution." The "worst case" of constructed wetlands applied as tertiary treatment solutions, and the "best case" of integrated constructed wetlands (ICWs) are considered in the following section. This comparison illustrates the multiple benefits achievable through harnessing wetland ecosystem services as "systemic solutions," including increased societal value achieved through optimizing outcomes across a range of ecosystem services while reducing capital and maintenance inputs and associated costs.

Constructed Wetlands Applied as Tertiary Treatment Solutions

Constructed wetland systems have been deployed in wastewater treatment processes since the 1950s, initially as tertiary "polishing" systems attached to conventional engineered wastewater treatment systems (Nuttall et al. 1997; Vymazal 2011).

Tertiary treatment wetland systems make positive contributions to the narrowly framed problems they are designed to manage. However, examination by Everard and McInnes (2013) found that these tertiary treatment constructed wetlands, as they are commonly implemented today, have high inputs and limited outputs.

Barriers to achieving wider benefits and reducing inputs are as much in the planning mindset as in the potential of the techniques themselves. Frequently, these systems are implemented purely as a "bolt-on" to traditional intensive treatment techniques, with "reeds in a box" solutions (plant-filled engineering systems) lacking hydrological connection with the surrounding landscape and providing minimal additional ecological benefits (Worrall et al. 1995). This is a consequence of narrow consideration of potential outcomes, generally focused purely on wastewater treatment, rather than recognizing the wide range of potential beneficial ecosystem services that wetlands provide. Hence, the many potential co-benefits that wetland systems can provide, such as carbon sequestration, landscape aesthetics, amenity and support for biodiversity, remain largely unrecognized (Chan et al. 2006; McInnes 2011).

Inputs to constructed wetlands designed narrowly as wastewater treatment systems include infrastructure development, pumping energy, earthworks, lining media, replacement of macrophytes and planting media, with associated supply chain issues, waste disposal, and transport. This differs little, if at all, from inputs to other alternative tertiary treatment options. Outputs are equally generally narrowly conceived, relating largely to reducing selected chemical parameters such as biological oxygen demand (BOD), ammonia, and phosphorus or other pollutants.

As one example, a rectilinear, concrete-walled wetland covering 2.1 ha was constructed at London Heathrow Airport for a cost of £1.2 million (2000 prices) primarily to treat glycol-contaminated runoff (Revitt et al. 2001). This draws into focus the potential disparity between the input costs and the output benefits. There may, in this case, be scope for better uses of this investment and physical footprint to achieve a greater range of ecosystem service outcomes rather than just solving one or a few focal issues. Alternative wetland design could, for example, also provide carbon sequestration, visual and noise screening, and potential settlement of fine airborne particulates by tall vegetation, as well as wider benefits including those considered when addressing "green infrastructure" later in this paper, cumulatively achieving greater societal value.

Appropriately designed constructed wetlands could provide multiple benefits for sustainable water management (Greenway 2005). However few, if any, other ecosystem service outcomes are currently routinely considered in design or operation relative to other tertiary treatment options, beyond potential efficiency gains for energy inputs and associated carbon emissions through the use of gravity-fed systems. The biological component – reeds and associated microorganisms – is considered within a narrow engineering paradigm that overlooks their wider potential benefits. Therefore, traditional approaches to constructed wetlands are characterized by limited outputs and high inputs to maximize generally narrow design objectives.

Vymazal (2010) summarized the range of investment costs associated with various constructed treatment wetland systems designed specifically to provide wastewater treatment. Total capital investment costs were observed to vary between US\$29 per m^2 in India to US\$335 per m^2 in Belgium. Some forms of constructed wetlands, such as free water surface flow systems which usually lack the requirement for the importation of a planting medium, represented a moderate cost saving, but subsurface flow systems carried a similar capital cost to conventional water treatment technologies. However, for gravity-fed systems, which obviate the need for pumping and hence associated costs, operational costs may be a factor of two to ten times lower than for conventional electromechanical technologies (Vymazal and Kröpfelová 2008; Vymazal 2010).

Notwithstanding there being almost parity between the capital costs associated with treatment wetlands and those required for conventional wastewater treatment technologies, opportunities to optimize the benefits provided are still the exception rather than the rule. This is despite the fact that the potential for treatment wetlands to deliver multiple benefits has been recognized for almost two decades (Knight 1997).

Integrated Constructed Wetlands (ICWs)

Conversely, integrated constructed wetland (ICW) systems are designed explicitly as low-input systems optimizing ecosystem service outcomes. Everard and McInnes (2013) found that ICWs represent a high level of benefits, optimized across ecosystem service categories rather than simply maximizing one or a few focal services while overlooking potential implications for others, while minimizing inputs through the use of natural processes.

ICWs explicitly integrate three objectives: water quantity and water quality management, including flood risk management; improving site aesthetic values through appropriate "landscape-fit"; and the improvement of biodiversity. The explicit integration of these objectives seeks to achieve positive synergies that might not otherwise be delivered through more traditional land management strategies (Harrington and McInnes 2009). Thus, ICWs are inherently designed to optimize ecosystem service outcomes while reducing inputs, including both capital and maintenance activities (Everard et al. 2012). They thereby represent a practical application of the Ecosystem Approach (Harrington et al. 2011). The ICW approach has now been developed beyond Ireland and is being applied elsewhere in the world (for example, Boets et al. 2011).

"Landscape fit" includes congruence both with the natural landscape (i.e., valleys in which water would naturally flow and wetlands form) and the socioeconomic landscape (addressing needs such as intercepting runoff from farm yards, urban sewage systems, field, or forests). Thus, "landscape fit" ensures that ICWs replicate natural landscape hydrological, biogeochemical, and other processes, therefore significantly reducing dependence on anthropogenic inputs.
